elevated insertion at these sites, prohibitive natural selection elsewhere, permissive selection at these sites, neutrality of replacement of previously acquired elements, or some combination of these factors. The genome data can be used to both form and address a series of testable hypotheses about the evolutionary dynamics of horizontal transfer. In terms of content, the CFT073 genome is notable for the absence of a type III secretion system, now a veritable diagnostic marker for gram-negative pathogens. It does, however, encode fimbrial adherence factors, including the well-characterized *pap* antigens, iron utilization systems, and a total of 1.2 Mb not seen in other sequenced *E. coli* genomes. Observed insertions, deletions, and rearrangements relative to islands characterized from other UTI associated *E. coli* may reflect the age of this lineage. Even horizontal transfers since the common ancestor of all *E. coli* could be 10 million years old (Reid *et al*., 2000). Other genome projects are underway for extraintestinal *E. coli* from this deep-branching lineage, including strain RS218, a K1-antigen *E. coli* associated with neonatal sepsis, and meningitis. Although this lineage of *E. coli* also includes diarrheal pathogens, no sequencing projects are yet underway for these strains.

5. Salmonella

Three complete *Salmonella enterica* genome sequences are available, one common laboratory strain of *S. enterica* Typhimurium (LT2) and two strains of *S. enterica* Typhi (CT18 and Ty2). *Salmonellae* are a common food-borne threat to public health and the livestock industry, and Typhoid fever caused by Typhi afflicts 16 million people a year. The *Salmonella* genomes tell a similar story to those of *E. coli*, with extensive differential horizontal transfer driving divergence between the Typhi and Typhimurium chromosomes. Among the more significant observations arising from the comparison of these genomes is the large number of pseudogenes in Typhi, distinguished by a stop codon that disrupts a continuous reading frame in Typhimurium and *E. coli* strains. Every sequenced genome of an enterobacterium contains some pseudogenes, but the elevated rate of pseudogene formation in Typhi has been suggested as a reflection of the reduction to a human-specific pathogen from an ancestor with a broader host range. There are 3000 or so orthologs shared between any pair of *Salmonella* and *E. coli* genomes. The genomes are largely colinear, except for a series of inversions about the origin and terminus of replication. Apart from those shared with *E. coli*, Typhi and Typhimurium have another 500 genes in common including the type III secretion systems, a number of effector proteins, and metal-ion transporters. Among the genes present in Typhi but not Typhimurium are chaperone–usher fimbrial systems, a hemolysin, homologs of the *Campylobacter* toxin *cdtB* and the *Bordetella pertussis* toxin genes *ptxA* and *ptxB*, a putative polysaccharide acetyltransferase, and many phage genes. Conversely, in Typhimurium but not Typhi are the pSLT plasmid genes and other fimbrial genes. Partial sequences are available for a number of other *Salmonella*, like *S.e*. Dublin, *S.e*. Enteritidis, and *S.e*. Paratyphi. Nonredundant microarrays representing the total set of genes identified in *Salmonella* genomes are providing a powerful tool for genotyping the many and diverse *Salmonella* serovars (Boyd *et al*., 2003).

6. Yersinia

Analyses of four complete genome sequences are available for representatives of the Genus *Yersinia*. Three are *Y. pestis*, the causative agent of bubonic and pneumonic plague, with selected strains from two distinct plague biovars: Medievalis (strains YPKIM) and Orientalis (CO92) (Parkhill *et al*., 2001b; Deng *et al*., 2002) and a recently complete sequence for strain 9001, an isolate that is virulent in mice but not in humans. *Y. pestis* is a relatively young species, having diverged from *Y. pseudotuberculosis* within the last 20 000 years (recently reviewed in Brubaker, 2004). Analyses of the complete sequence of *Y. pseudotuberculosis* strain IP32953 and PCR-based, microarray-based, and sequence-based comparisons with *Y. pestis* genomes have just been published, revealing that very few events were required to evolve plague, a highly virulent pathogen, from a less virulent ancestor (Chain *et al*., 2004). In total, only 32 genes, clustered in 6 islands, are found in all *Y. pestis* chromosomes surveyed, but not in *Y. pseudotuberculosis*. There are also two *Y. pestis*-specific plasmids (a third, pCD1 is shared by both species). *Y. pestis* genomes also tend to show a relatively large number of pseudogenes relative to *Y. pseudotuberculosis*. The *Y. pestis* 91001 genome is quite different from the other two *Y. pestis* and includes an additional plasmid containing genes for a type IV secretion system as well as many chromosomal changes, with 141 likely pseudogenes.

Given the close relationship of all *Y. pestis*, it is not surprising that the CO92 and KIM genomes are alignable across 95% of their length (Deng *et al*., 2002). Even with this limited variability among the complete *Y. pestis* genomes, the sequences are proving useful. Microarray-based genotyping has been used to characterize live plague vaccine strains and natural isolates (Hinchliffe *et al*., 2003; Zhou *et al*., 2004a; Zhou *et al*., 2004b). Together, these comparisons reveal roughly 25 islands polymorphic in the *Y. pestis* population. Although *Y. pestis* show a much lower degree of gene acquisition by horizontal transfer than *E. coli* strains, *Y. pestis* genomes show much higher levels of rearrangement. Alignment of the CO92 and KIM genomes divides the chromosomes into at least 27 blocks of sequences that are colinear. Most disruptions in colinearity result from a series of inversions around the origin and terminus of replication, typically bounded by repetitive elements (Deng *et al*., 2002). A large number of rearrangements also differentiate the 91001 genome from the other two pestis chromosomes. This propensity for rearrangement is not shared with *Y. pseudotuberculosis* (Chain *et al*., 2004).

Just over half of the genes in each *Y. pestis* genome have putative orthologs in *E. coli*, *Salmonella*, or *Erwinia*. These, almost certainly, are components of the core ancestral chromosome, including most basic metabolic genes, global regulators, and many transport proteins. Although colinearity with these more distantly related taxa appears to be limited to segments of one or a few operons, dotplots of these putative orthologs show a characteristic “X” shape (Eisen *et al*., 2000), reflecting a series of inversions about either the origin or terminus of replication relative to the ancestral state. Putative orthologs observed off the main diagonals of the plot may reflect small translocations, or differential loss or gain of paralogous sequences that are currently mistaken as orthologous. Resolution will require additional phylogenetic analysis, and, possibly, additional genome-scale data.

Genome sequencing is complete for *Y. enterocolitica,* a close relative of *Y. pestis* that causes gastroenteritis. Complete annotation and publication of the sequence is anticipated later this year.

7. Plant-pathogenic enterobacteria

Recently, the publication of a genome for the pytopathogen *Erwinia carotovora* ssp. atroseptica allowed for the first comparison of plant and animal pathogenic enterobacteria. The reported number of genes shared between *E. c. atroseptica* and any *E. coli*, *Yersinia,* and *Salmonella* genome is about 2300. Among those genes not found in the animal-associated organisms are a battery of plant cell wall–degrading enzymes and an impressive array of secretion systems: type II, type III, type IV, TAT, and fimbrial. The contents of the likely horizontally acquired segments of these genomes show similarities with the other enterobacteria. They include secretion systems and numerous iron-uptake systems. However, unlike the animal-associated enterobacteria, there are not large numbers of fimbrial operons, suggesting that these extracellular structures may be less important for the plant-pathogenic lifestyle. A genome project is underway for another soft-rot associated plant pathogen, *Erwinia chrysanthemi* strain 3937. Although the common usage of the genus *Erwinia* for these two organisms suggests a close relationship, a series of recent taxonomic revisions suggest that they are quite different, and the genomes are expected to show substantial divergence. An entirely separate lineage of plant pathogens, many also known as *Erwinia*, are associated with diseases quite distinct from soft-rot. Genome projects for two of these are underway, *Erwinia amylovora*, the causative agent of “fire blight” of apples and pears, and *Pantoea stewartii*, a pathogen of sweet corn and maize. The *P. stewartii* genome includes 10–13 stable plasmids totaling a quarter of the genome.

8. Insect-associated enterobacteria

Photorhabdus luminescens is an enterobacterium found as a symbiont of soil entomopathogenic nematodes and a pathogen of diverse insects. The *P. luminescens* life cycle includes a symbiotic stage in the nematode gut and a virulent stage in the insect larvae that is killed through toxemia and septicemia. The *P. luminescens* genome (Duchaud *et al*., 2003) encodes a large number of adhesins, hemolysins, lipases, proteases, and antibiotic biosynthesis genes. These proteins are likely to play a role in the elimination of competitors, colonization of the host, and invasion and utilization of the insect cadaver. The genome encodes more predicted toxin-encoding genes than any other complete genome. The diversity of toxins may be related to pathogenicity on a wide variety of insect species. A number of secreted proteins were identified that likely play a role in bioconversion of the insect cadaver. Comparison of the *P. luminescens* genome to *Y. pestis* revealed 2107 orthologous genes, including some that are not shared with *E. coli*. The genome contains a large number of IS elements (about 195) and an astounding 711 inverted repeats of

the enterobacterial repetitive intergenic consensus (ERIC) sequence that has only 21 copies in *E. coli* K-12.

Genome sequences have been completed for five bacterial endosymbionts of insects, three from the genus *Buchnera* (aphid host), *Blochmannia floridanus* (carpenter ant host), and *Wigglesworthia glossinidia* (tsetse fly host). These symbionts reside in specialized host cells called bacteriocytes, and the bacteria are transmitted maternally during insect development. The symbioses all seem to involve insect hosts that feed on nutrient sources lacking in key metabolites; amino acids in the case of phloem-feeding aphids and carpenter ants, which are believed to subsist primarily on the honeydew of phloem-feeding insects, and vitamins in the case of tsetse flies that feed on vertebrate blood. The bacteria are believed to supplement their hosts with these key metabolites in exchange for metabolic products that the bacteria require. An obvious consequence of these long-term associations, and the stabile environments provided by hosts, is an extreme reduction in genome size in all of these lineages. Genomes from all three genera have lost many typical enterobacterial genes such as those involved in transport and transcriptional regulation activities. Each of the three endosymbiont lineages has retained a somewhat different subset of genes from the ancestral genome that likely reflect the differing nutritional needs of their host species. *Wigglesworthia,* for example, contains many genes involved with cofactor biosynthesis that are absent in *Buchnera* that contains more genes involved in amino acid biosynthesis. A less obvious consequence of this endosymbiont lifestyle is an increase in the rate of nucleotide substitution and reduction in the rate of genome rearrangement compared with other free-living enterobacteria. This apparent paradox can be explained by the types of sequences missing from these genomes that include most of the repetitive elements, such as IS, multiple rRNA operons, and recombination-associated genes that are associated with genome rearrangements, and genes encoding repair and stress-response functions that are associated with maintaining sequence integrity. Interestingly, some of the genes maintained in *Blochmannia* and *Wigglesworthia* encode components of the flagellar machinery and cell wall constituents that suggest more complex interactions with their hosts than currently known.

9. Beyond genome sequencing

As new sequences accumulate, existing genomes of enterobacteria are being put to work in a multitude of ways. Applications of the sequences include hypothesis-driven research like experimental verification of roles of putative new virulence factors identified in the genomes. The distribution of individual islands identified through comparative genomics in populations of pathogens has led to correlations of epidemiologically relevant characteristics with genomic markers. Other types of polymorphisms identified by analyzing and comparing genomes provide additional means for subtyping isolates of pathogens. High-throughput multilocus PCR assays and microarray technologies are beginning to provide genome-scale subtyping alternatives. *E. coli* K-12, with its large complement of experimental data, is a choice target for modeling cell growth, metabolism, and regulation, giving rise

to novel systems-based approaches to understanding the relationship between genotypes and phenotypes.

Specialist Review

Genomics of the *Mycobacterium tuberculosis* complex and *Mycobacterium leprae*

Stephen V. Gordon
Veterinary Laboratories Agency, New Haw, UK

Roland Brosch
Institut Pasteur, Paris, France

1. Introduction

Mycobacterial infectious diseases are among the most ancient diseases known to man, yet they continue to cause a staggering burden of death and morbidity in the modern world. This is in spite of the fact that the causative agents of tuberculosis and leprosy, *Mycobacterium tuberculosis* and *Mycobacterium leprae* respectively, were among the first pathogens ever to be identified, with Hansen identifying *M. leprae* in 1874 and Koch describing the tubercle bacillus in 1882. Our inability to eradicate these infections is due to a combination of factors, not least of which is the slow pace of research on these organisms, primarily due to the slow growth of *M. tuberculosis* (3 weeks to form visible colonies), and the resistance of *M. leprae* to all attempts at axenic culture.

The *M. tuberculosis* complex is a group of highly related bacteria that are the etiological agents of tuberculosis (TB). The type strain of the complex is *M. tuberculosis*, the agent of human tuberculosis that causes 8 million new infections and kills over 2 million humans a year. The other main member is *Mycobacterium bovis*, the cause of tuberculosis in a range of domesticated and wild mammals, and man, that is responsible for annual losses of approximately $3 billion to world agriculture. At the beginning of the twentieth century, Calmette and Guérin at the Pasteur Institute of Lille used *M. bovis* as the starting point in their search for a vaccine against tuberculosis, and after 13 years of in vitro passage, produced the *M. bovis* BCG strain, currently the most widely used vaccine in the world. The remaining members of the complex are less well known: *M. africanum* and *M. canettii* cause limited numbers of human tuberculosis cases in Africa; *M. caprae* causes tuberculosis in goats and other mammals; *M. pinnipedii* has been found in seals with tuberculosis. *M. microti* is the agent of tuberculosis in wild rodents and voles, but most strains are attenuated for man; this feature led to its use as a live-attenuated vaccine against tuberculosis. However, the *M. tuberculosis* complex are not the only significant pathogens found in the genus.

Leprosy is characterized by peripheral nerve damage and skin lesions, ultimately leading to progressive debilitation. Although the WHO had aimed to eliminate leprosy by 2000, meaning a reduction in prevalence to below 1 case per 10 000 of the population, this target was not achieved. Instead, leprosy is still a major cause of suffering in many parts of the world, with the number of new cases actually increasing.

The third most common mycobacterial disease of immunocompetent people after tuberculosis and leprosy is Buruli ulcer, characterized by debilitating chronic skin lesions that are caused by *Mycobacterium ulcerans*. The prevalence of Buruli ulcer throughout West Africa appears to have increased dramatically since the late 1980s, but the disease also occurs in other parts of the world. Unlike other mycobacterial pathogens, *M. ulcerans* is found mainly at an extracellular location during infection and produces a toxin, mycolactone (George *et al*., 1999). Treatment of the disease is usually by surgical excision of infected and surrounding tissue, as the organism in situ is unresponsive to drug therapy. The mode of transmission of *M. ulcerans* has not yet been completely elucidated, but a transmission chain involving aquatic insects seems likely (Marsollier *et al*., 2002).

Clearly, there is a desperate need for new control strategies if we are to reduce the burden exacted by the mycobacterial pathogens. It was against this backdrop that the genome sequencing projects of *M. tuberculosis*, *M. leprae*, *M. bovis*, *M. bovis* BCG Pasteur, and *M. ulcerans* were initiated. This chapter shall deal with the insights we have gained into the biology of these pathogens through exploration of their genome sequences, and highlight the new research that is developing promising leads into disease control. As a stylistic point, we shall use the *M. tuberculosis* H37Rv genome sequence as the reference, with "Rv" denoting genes from this sequence, while "Mb" indicates *M. bovis* and "ML" indicates *M. leprae* genes. At the time of writing, the genome sequence of *M. ulcerans* is not yet published, but initial sequence analysis has shown that the capacity of *M. ulcerans* to produce its very potent macrolide toxin is linked to the presence of a large 174-kb plasmid harboring the genes involved in the synthesis of mycolactone (Stinear *et al*., 2004). This is the first example of a plasmid-encoded mycobacterial virulence factor.

2. The *M. tuberculosis* complex: genome highlights

The complete genome sequences of two strains of *M. tuberculosis* (H37Rv and CDC1551) and one of *M. bovis* (AF2122/97) are available at the time of writing (Garnier *et al*., 2003; Cole *et al*., 1998; Fleischmann *et al*., 2002). Examination of the genomes underlined the high level of genetic similarity across the members of the complex, with *M. bovis* proving >99.9% identical to the *M. tuberculosis* strains (Garnier *et al*., 2003). Incomplete sequence data is also available for the "210 Beijing" strain of *M. tuberculosis* (**http://www.tigr.org/tdb/mdb/mdbinprogress.html**), as well as for *M. bovis* BCG Pasteur and *M. microti* (**http://www.sanger.ac.uk/Projects/Microbes/**). The exploitation of these data is providing new insights in the evolution, physiology, and virulence of the *M. tuberculosis* complex.

The original genome publications and subsequent reviews have dealt in detail with the initial findings from the completed genome sequences (Brosch *et al*., 2000a; Brosch *et al*., 2000b; Cole *et al*., 1998; Gordon *et al*., 2002; Garnier *et al*., 2003; Fleischmann *et al*., 2002), and it is not our wish to go over this territory again in detail. Rather, we will briefly summarize common features across the genomes of the *M. tuberculosis* complex, highlighting significant differences and new work that provides insight into the biology of the complex.

2.1. Genome structure

As the type strain of the complex, *M. tuberculosis* H37Rv was the first member to have its genome sequenced, revealing a single circular chromosome, ∼4.4 Mb in size with a G+C content of 65.6% (Cole *et al*., 1998). The *M. tuberculosis* CDC1551 sequence showed a similar genome size, with no evidence of extensive translocations, transversions, or duplications relative to the H37Rv strain (Fleischmann *et al*., 2002). An intriguing difference was noted in the ratio of synonymous (silent) to nonsynonymous substitutions (Ks/Ka) between the two strains, with a value of 1.6 (Fleischmann *et al*., 2002). Compared to other bacteria, where a range between ∼8 and 26 as a result of purifying selection acting against amino acid changes is usual, this was surprising. The *M. bovis* sequence revealed a similar overabundance of nonsynonymous substitutions (Garnier *et al*., 2003), suggesting that among these members of the complex, purifying selection had not had time to act, underlining the relatively recent divergence of these strains.

The *M. bovis* genome showed colinearity with the *M. tuberculosis* strains, and no evidence of extensive translocations, duplications, or inversions. Prior to the availability of the *M. bovis* genome sequence, comparative analyses with members of the *M. tuberculosis* complex had been performed using hybridization-based methods, exploiting this high degree of sequence identity (Gordon *et al*., 1999a; Behr *et al*., 1999). This revealed 11 deletions from the genome of *M. bovis*, ranging in size from ∼1 to 12.7 kb, and these were confirmed by the sequence data. Surprisingly, the *M. bovis* sequence contains only one locus in *M. bovis*, termed TbD1 for *M. tuberculosis* specific deleted region 1, which is absent from the majority of extant *M. tuberculosis* strains (Garnier *et al*., 2003). Therefore, at a gross level, deletion has been a major mechanism in shaping the *M. bovis* genome.

2.2. The PE and PPE proteins

Analysis of the *M. tuberculosis* H37Rv genome revealed a number of unexpected findings, not least of which was the presence of two families of repetitive sequences that encode the PE and PPE proteins (Cole *et al*., 1998). The PE family is so called after the presence of the motif proline-glutamic acid (PE) at positions 8 and 9 in a conserved N-terminal region of approximately 110 amino acids. The family contains 99 members that can be subdivided into the PE and PE-PGRS subfamilies, the latter group containing multiple repeats of a glycine-glycine-alanine or glycine-glycine-asparagine. Members of the PPE family contain the

motif proline-proline-glutamic acid (PPE) at positions 7–9, followed by a variable C-terminal region. This family contains 68 members, which can be grouped into three subfamilies. The first of these families contains the major polymorphic tandem repeat (MPTR) sequences that are characterized by asparagine-rich repeats.

The PGRS and MPTR sequences had originally been described as genetically hypervariable loci (Poulet and Cole, 1995; Hermans *et al*., 1992). Use of PGRS-based probes revealed a high degree of genetic differences between tubercle bacilli, allowing the loci to be exploited as epidemiological markers for typing of *M. tuberculosis* complex strains. The availability of genome data has permitted comparative analyses to identify alleles of the PPE proteins that vary across strains. For example, between *M. bovis* AF2122/97 and *M. tuberculosis* H37Rv, there are blocks of sequence variation in genes encoding 29 different PE-PGRS and 28 PPE proteins. While the majority of proteins are identical between the human and bovine bacilli, ∼60% of the PE and PPE proteins differ across these two pathogens, a feature that is clearly at odds with the rest of the genome. This may indicate that the PE and PPE genes can support extensive sequence polymorphism that may provide a source of variation for selective pressures to act upon.

In this light, it is intriguing that there is now a considerable body of evidence to suggest that at least some of the PE and PPE proteins are surface exposed and may play a role in adhesion or immune evasion. Delogu and colleagues have shown that the PE-PGRS Rv1818c is surface exposed, with the PE domain involved in subcellular localization and the PGRS domain influencing cell shape (Delogu *et al*., 2004). Similarly, Banu *et al*. (2002) have shown that polyclonal antibodies raised against the PE-PGRS Rv1411c could be used to surface-stain *M. tuberculosis*. Interestingly, two studies have found that the PPE Rv1753c is essential for growth in vitro (Lamichhane *et al*., 2003; Sassetti *et al*., 2003). However, considering that there are over 160 genes encoding PE and PPE proteins, genome-wide mutagenesis studies have identified only a few members whose disruption leads to attenuation. Hence, transposon insertion into the PE and PPE genes Rv3018, Rv3872, and Rv3873 attenuated the mutant, but this may have been due to polar effects on nearby regions that code for secretion of ESAT-6 family members (Camacho *et al*., 1999; Sassetti and Rubin, 2003). These findings suggest functional redundancy across the PE and PPE proteins. Indeed, the expression of PE and PPE genes has been shown to be controlled by a variety of independent systems, and they show little evidence for global coregulation (Voskuil *et al*., 2004).

2.3. Cell envelope and antigenic variation

Cell walls of pathogenic bacteria are known to show variation in protein sequences and macromolecular composition, reflecting selective pressures on these structures; the PE and PPE proteins offer a case in point. However, this holds true for other cell wall associated proteins, with the greatest degree of sequence variation between the human and bovine bacilli found in genes encoding cell wall and secreted proteins. Comparison of the *M. bovis* and *M. tuberculosis* sequences revealed variation in genes encoding lipoproteins, with *lppO*, *lpqT*, *lpqG*, and *lprM* deleted or frameshifted in *M. bovis* (Garnier *et al*., 2003). Similarly, the *M. bovis rpfA*

gene, one of a five-membered family encoding secreted proteins that promote the resuscitation of dormant or nongrowing bacilli, shows an in-frame deletion of 240 bp that leads to the synthesis of a shorter protein. Whether this affects the function of the protein, or again reflects antigenic variation, is unclear.

A group of known antigens affected by deletions from *M. bovis* is the ESAT-6 family. The ESAT-6 protein was originally described as a potent T-cell antigen secreted by *M. tuberculosis*, and belongs to a >20-membered family that contains other T-cell antigens such as CFP-10 and CFP-7. The demonstration of an interaction between ESAT-6 and CFP-10 suggested that other members of the family may also act in pairs, and this appears to be the case (Okkels and Andersen, 2004; Renshaw *et al*., 2002). Six ESAT-6 proteins, encoded by Rv2346c, Rv2347c, Rv3619c, Rv3620c, Rv3890c (Mb3919c), and Rv3905c (Mb3935c) in *M. tuberculosis*, are missing or altered in *M. bovis*. The consequences of their loss are difficult to predict, although they may impact on antigen load either singly or in combination.

Differences are also seen between *M. tuberculosis* and *M. bovis* in genes encoding the synthesis (*pks*), or transport (*mmpSL*) of polyketides and complex lipids with polyketide moieties. These lipids are major factors in inducing host pathologies that create more favorable environments for the pathogens. The genes *pks1, mmpL13*, and Mb1695c (a putative macrolide transporter adjacent to the *pks10/7/8/17/9/11* cluster) could be translated to functional products in *M. bovis* but are disrupted in *M. tuberculosis*. The opposite is the case (i.e., disrupted in *M. bovis*) for the linked *pks6* and *mmpL1* genes, and *mmpL9*. It has been shown functionally that *pks1* codes for the biosynthesis of the major phenolic glycolipid (PGL) of *M. bovis* and *M. canettii* as in strains where *pks1* is disrupted, such as *M. tuberculosis* H37Rv, where no PGL is produced (Constant *et al*., 2002). Other genes from the flanking regions of the *pks1* locus, such as Rv2958c encoding a putative glycosyl transferase, are involved in the modification of the sugar component of the PGL molecules (Perez *et al*., 2004). As the predicted amino acid sequence for Rv2958c and its *M. bovis* ortholog Mb2982c are only 83% identical, it seems possible that this difference could alter the PGL sugar modifications in *M. bovis* and hence lead to antigenic variability.

The TbD1 locus, containing the gene *mmpS6* and the 5′ region of *mmpL6*, is absent from the majority of *M. tuberculosis* strains but intact in *M. bovis* strains (Brosch *et al*., 2002). Deletion of TbD1 may prevent trafficking of specific lipids to the cell wall of *M. tuberculosis*. However, according to the sequence characteristics, the deletion of the TbD1 region resulted in the fusion of the remaining *mmpS6* and *mmpL6* fragments. It has not yet been determined whether the MmpS/MmpL6 hybrid protein is expressed in TbD1 deleted strains or has a specific function in them (Figure 1). Furthermore, a deletion in *M. bovis* of 808 bp is proximal to the TbD1 region and truncates the *treY* gene. As *treY* encodes a maltooligosyltrehalose synthase, an enzyme in a pathway for trehalose production (two other pathways are intact), its deletion in *M. bovis* may have an effect on the range of trehalose-based glycolipids that are produced.

2.4. *Metabolic insight*

The mycobacterial cell wall has been the target of in-depth studies for many decades, revealing a complex repertoire of unusual lipids that give the structure its

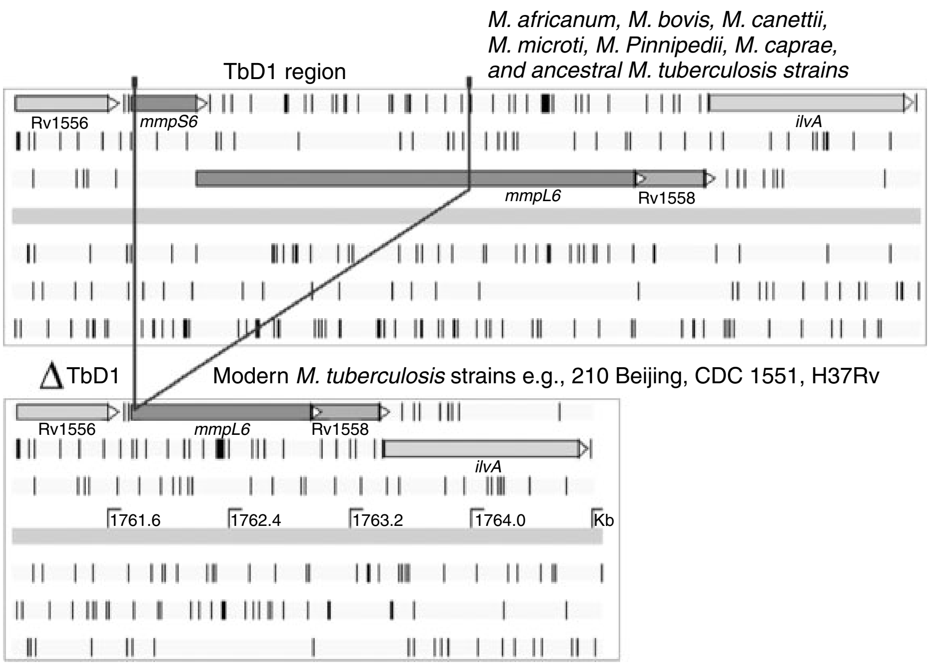

Figure 1 The TbD1 deletion locus. The figure shows a schematic of the TbD1 locus in *M. tuberculosis* (ΔTbD1) and in other strains of the complex where the region is intact. The six reading frames are shown, with CDSs represented as pointed boxes showing the direction of transcription, and stop codons shown as small vertical bars. Gene designations are as described on the TubercuList database (**http://genolist.pasteur.fr/TubercuList/**)

unique architecture. Hence, it could have been expected that the mycobacterial genome would encode sophisticated machinery for lipid metabolism; however, it was still unexpected that over 9% of the genome coding capacity of H37Rv would be dedicated to lipids. A striking level of redundancy in lipid metabolic genes was apparent in the *M. tuberculosis* H37Rv genome with 36 *fadD* alleles encoding acyl-CoA synthase, 36 *fadE* genes encoding acyl-CoA dehydrogenase, and 21 *echA* genes for enoyl-CoA hydratase/isomerase (Cole *et al*., 1998). The apparent redundancy in lipid enzymes may however need to be readdressed in the light of recent work with the *fadD* genes. Gokhale and colleagues have shown that some of the *fadD* alleles do not encode fatty acyl-CoA ligases but instead code for a new class of fatty acyl-AMP ligases that are linked to a proximal *pks* gene and are dedicated to the synthesis of unique polyketides (Trivedi *et al*., 2004). It is therefore possible that the apparent redundancy in lipid enzymes hides novel enzyme activities.

An example of the power of comparative genomics is evidenced by the elucidation of the reason for one of the key in vitro differences between *M. bovis* and *M. tuberculosis*. The bovine bacillus requires pyruvate to be added to media where glycerol is the sole carbon source, presumably reflecting a defect in the metabolism of glycerol by *M. bovis*. Trawls of the *M. bovis* genome sequence revealed a point mutation in the gene for pyruvate kinase (PK), the enzyme that catalyzes the final irreversible step in glycolysis, the dephosphorylation of phosphoenolpyruvate to

Strain	Sequence (codons 215-225)	PK activity
M. tuberculosis H37Rv	GTG ATC GCC AAG CTG GAG AAG CCG GAA GCC ATC	Yes
M. bovis 2122/97	GTG ATC GCC AAG CTG GAT AAG CCG GAA GCC ATC	No
M. bovis 1307/01	GTG ATC GCC AAG CTG GAT AAG CCG GAA GCC ATC	No
M. bovis BCG	GTG ATC GCC AAG CTG GAG AAG CCG GAA GCC ATC	Yes
M. bovis AN5	GTG ATC GCC AAG CTG GAG AAG CCG GAA GCC ATC	Yes
	V I N K L E/D K P E A I	

(a)

(b)

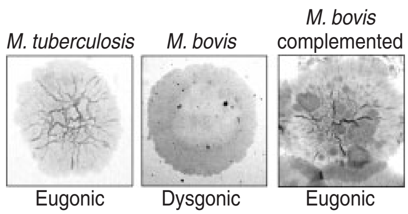

Figure 2 Pyruvate kinase analysis across *M. bovis* and *M. tuberculosis*. (a) A sequence alignment of codons 215–225 of the *pykA* gene is shown from *M. tuberculosis* H37Rv, *M. bovis* 2122/97, *M. bovis* 1307/01 (a recent field isolate), *M. bovis* BCG Pasteur, and *M. bovis* AN5 (used for production of bovine tuberculin). Pyruvate kinase is shown as active (yes) or inactive (no). The latter two strains were adapted for growth on glycerol, a process that was selected for an active PK. (b) Growth of strains on glycerol-containing medium. Strains are described as eugonic (abundant growth in the presence of glycerol, dry, crumbly, and raised colonies) or dysgonic (sparse growth on solid medium containing glycerol, colonies moist, glossy, and flat). The picture shows the colony morphology of *M. tuberculosis* H37Rv, *M. bovis* wild-type, *pykA*$^+$ complemented *M. bovis*, and *M. bovis*/plasmid control, after three-week growth on Middlebrook 7H11 agar plates with 0.05% glycerol and antibiotics as appropriate

pyruvate. The mutation was predicted to affect binding of the Mg^{++} cofactor to PK, and enzyme analysis showed that *M. bovis* lacked pyruvate kinase activity (Figure 2a). Hence, in *M. bovis*, glycolytic intermediates are blocked from feeding into oxidative metabolism, meaning that in vivo *M. bovis* must rely on amino acids or fatty acids as a carbon source for energy metabolism. Complementation of *M. bovis* with the *pykA* allele from *M. tuberculosis* H37Rv permitted abundant growth of the recombinant *M. bovis* on glycerol-containing media. However, the complemented strain also displayed the characteristic "eugonic" colony morphology that is classically associated with *M. tuberculosis* strains; *M. bovis* strains normally display "dysgonic" growth on media containing glycerol (Keating *et al*., submitted; Figure 2b). Hence, it appears that the presence of a functioning PK enzyme is intimately linked to the surface features of the bacillus.

Although the tubercle bacilli are classified as aerobic organisms, the genome data revealed the potential for microaerophilic and anaerobic respiration. An operon, *narGHJI*, is present, encoding a nitrate reductase that allows utilization of nitrate as a terminal electron acceptor. Investigating the role of nitrate reductase, Bange and colleagues generated a *narG* mutant of *M. bovis* BCG (Weber *et al*., 2000). Immunodeficient mice infected with the *narG* mutant developed smaller granulomas than those infected with the wild type. Furthermore, mice infected with the mutant presented no clinical signs of disease after more than 200 days. It, therefore, appears that the ability to respire anaerobically contributes to virulence. It is also noteworthy that one of the classical microbiological methods to differentiate *M. bovis* from *M. tuberculosis* is based on nitrate reductase activity; *M. tuberculosis* reduces nitrate to nitrite while *M. bovis* performs this reduction very poorly. Bange

and colleagues have also shown that this defect in nitrate reductase activity is due to a point mutation in the promoter of the *M. bovis narGHIJ* cluster (Stermann *et al*., 2004).

2.5. Repetitive DNA

In contrast to the high degree of nucleotide identity across the *M. tuberculosis* complex, repetitive DNA acts as a substrate for the generation of genetic diversity, for example, through recombination between repeats or transposition of IS elements. Analysis of the *M. tuberculosis* H37Rv genome revealed 56 loci with similarity to IS elements, occupying approximately 77 kb (Gordon *et al*., 1999b). These elements could be classified into the major IS families such as IS*3*, IS*5*, or IS*21*, with the most abundant IS in the genome being IS*6110,* an IS*3* family member that varies from 0 to >25 copies across strains. This divergence in copy number between *M. tuberculosis* isolates is the basis of the IS*6110*-based molecular typing system. What was originally thought to be a novel IS grouping, the IS*1535* family, was identified that contained six intact elements and one pseudogene. However, with the increase in genome sequence from other bacteria, it is now apparent that the IS*1535* group forms part of the IS*605* family (as defined in the IS Finder database, **http://www-is.biotoul.fr/is.html**).

A novel class of repeats was uncovered by Supply and colleagues and designated "Mycobacterial Interspersed Repetitive Units", or MIRUs (Supply *et al*., 1997). These elements are dispersed throughout the genomes of the *Mycobacterium* complex strains and *M. leprae.* They display no significant homology to other bacterial repetitive sequences, and in contrast to many other repeat elements, they do not contain obvious palindromic structures. Intriguingly, many MIRUs are located intergenically, overlapping termination and initiation codons of adjacent genes, and they contain small CDSs oriented in the same translational direction as the contiguous genes, an arrangement that strongly suggests translational coupling. MIRUs have also been developed as a powerful typing system for the *M. tuberculosis* complex, and Supply and colleagues have used data from 12 MIRU loci across a bank of *M. tuberculosis* strains to show that the population structure of *M. tuberculosis* was clonal (Supply *et al*., 2003).

The so-called direct repeat (DR) region harbors numerous direct repeat units of 36 bp that are interspersed with 27- to 41-bp segments of unique sequence. Recombination events between the direct repeats and/or copies of IS*6110* elements inserted in this genomic region create polymorphism across strains of the *M. tuberculosis* complex that can be visualized and distinguished by a technique called spoligotyping (Kamerbeek *et al*., 1997). Comparative analysis of information from spoligotype with analysis of genome deletions, point mutations, and MIRU variation has shown that combinations of these molecular characteristics appear to be strictly correlated in strains of the *M. tuberculosis* complex, allowing the development of rapid strain identification and typing strategies (Banu *et al*., 2004). Figure 3 shows an example of how these data can be used to group strains and define certain strain families, such as the so-called *M. tuberculosis* Beijing family, which is a particularly successful clonal group.

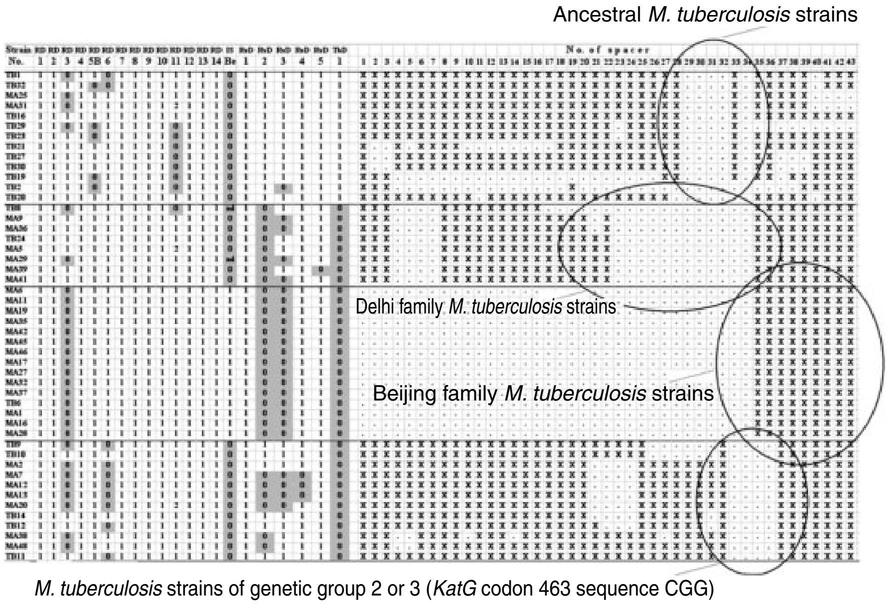

Figure 3 Genetic characterization of *M. tuberculosis* clonal groups. A range of molecular markers were screened against the panel of *M. tuberculosis* strains described in Banu *et al*. (2004). PCR results for the "regions of difference", or RD, are shown, with 0 = region not present; 1 = region present; 2 = both internal and flanking primers gave a product. "Be" designates the presence of the IS *6110* element in the *dnaA-N* locus, which is indicative of the Beijing family of *M. tuberculosis*. Spoligotype results are also shown against the standard set of 43 spacers, where an "X" shows that the spacer is present, while "-" designates a deleted spacer. Clonal groups of *M. tuberculosis* strains have clear combinations of markers; ND, not determined

Two prophage-like elements, phiRv1 and phiRv2, are present on the *M. tuberculosis* H37Rv genome. The presence and position of these prophages is variable across sequenced members of the *M. tuberculosis* complex, with phiRv2 not present in *M. bovis* AF2122/97, *M. bovis* BCG missing both prophages, and with *M. tuberculosis* CDC1551 having phiRv2 integrated at a different locus than H37Rv. The variation in integration sites of phiRv2 is due to its attachment site being contained in at least four copies of the REP13E12 repeats, a family of seven repeats that range in size from 1.3 to 1.4 kb and so called after the annotation of the first element on cosmid MTCY13E12 (Cole *et al*., 1998).

2.6. *Evolution*

Comparative studies of *M. bovis* BCG, *M. bovis*, and *M. tuberculosis* H37Rv identified several regions of difference (RD) absent from BCG (Mahairas *et al*., 1996; Gordon *et al*., 1999a; Behr *et al*., 1999). From close inspection of these regions, it was apparent that several segments of conserved genes were missing from BCG and *M. bovis* that were still intact in *M. tuberculosis*, arguing against the possibility that the RD regions resulted from the insertion of genomic

material into *M. tuberculosis,* but rather represent deletions (Brosch *et al*., 2001). Together with the finding that the *M. tuberculosis* complex has a clonal population structure, with no evidence of horizontal transfer (recombination) between strains (Supply *et al*., 2003), deletion events can be used as unidirectional markers for phylogenetic reconstruction. Using deletion analysis, we were able to generate a novel evolutionary scenario for the *M. tuberculosis* complex, based on the successive loss of DNA from certain lineages (Brosch *et al*., 2002) that contradicted previous theories. It had been assumed that *M. tuberculosis* arose at the time of the domestication of cattle, approximately 10 000–15 000 years ago, when the bovine tubercle bacillus was transmitted to the human population. This was based on the observation that extant *M. bovis* strains have a wide host range, infecting wild and domesticated mammals as well as man, while *M. tuberculosis* appears restricted to humans. The new scenario refutes the notion that modern strains of *M. bovis* should lie closer to the common ancestor of the complex, and in fact places the common ancestor closer to *M. tuberculosis* and/or *M. canettii*. Since then, this phylogeny has been backed up by other studies (Gutacker *et al*., 2002; Mostowy *et al*., 2002) and the *M. bovis* genome sequencing project, which found no unique genes per se in *M. bovis* relative to *M. tuberculosis* (Garnier *et al*., 2003).

Deletion analysis has also provided fundamental insight into the evolutionary history and transmission patterns of *M. tuberculosis*. Using microarray analysis of 100 epidemiologically well-defined *M. tuberculosis* isolates from San Francisco, Small and colleagues were able to show that strains show close association with their host populations over time, so much so that a patient's region of birth could be used as a predictor of strain carriage (Hirsh *et al*., 2004). Their analysis confirmed the lack of any significant horizontal gene transfer in *M. tuberculosis*, and also showed that deletions were grouped in the genome, revealing regions of the genome that are prone to deletions (Hirsh *et al*., 2004; Tsolaki *et al*., 2004). The functional implications of deletions were less clear cut; on balance, it appeared that most deletion events were slightly deleterious, with a minority, such as loss of the *katG* region that imparts resistance to the front-line drug isonizaid, offering any obvious selective advantage (Tsolaki *et al*., 2004).

3. Genomics of the leprosy bacillus

3.1. Genome downsizing

The genome of *M. leprae* consists of a single circular chromosome of 3 268 203 bp (Cole *et al*., 2001a). The most remarkable feature of the genome is the wholesale loss of genetic information, with a coding capacity of less than 50% compared to 90% in *M. tuberculosis*. This reduction in coding capacity is due both to the deletion of chromosomal regions and the accumulation of pseudogenes. These decayed gene remnants are abundant and presumably reflect the removal of functions superfluous to the in vivo growth of the bacillus; alternatively, they may indicate an accumulation of deleterious mutations as the organism goes through bottlenecks in its secluded niche.

Potentially, the most interesting genes from the point of view of understanding *M. leprae* are the 165 genes that have no counterpart in other sequenced mycobacteria. While a putative function can be ascribed to 29 of these genes, 136 have no similarity to other genes currently in sequence databases, and this suggests that their functions may be specific to the leprosy bacillus. From a clinical point of view, these genes are attractive candidates for specific diagnostic reagents.

Perhaps the most striking difference in gene families between the leprosy and tubercle bacilli is the case of the PE and PPE proteins. While these two families account for 167 genes in *M. tuberculosis*, only nine intact PE or PPE genes could be identified in *M. leprae*, with complete loss of the PE–PGRS subfamily. This most likely reflects both downsizing in *M. leprae* and expansion in *M. tuberculosis*. Interestingly, some of the intact PE and PPE genes in *M. leprae*, such as ML1828, ML1182, or ML0411, are in gene-poor regions or surrounded by pseudogenes (Cole *et al*., 2001a). Hence, while neighboring loci were deleted or accumulated mutations, these PE and PPE genes were maintained, suggesting a requirement for at least a minimal set of functional PE and PPE proteins.

Indeed, there are some parallels with gene loss between *M. bovis* and *M. leprae*, with many of the common genes either deleted or inactivated in the two organisms. For example, genes involved in transport and cell surface structures *(pstB*, *ugpA, mce3A-F, lppO, lpqG, lprM, pks6, mmpL1, mmpL9,* Rv1510, Rv1508, Rv1371), fatty acid metabolism (*fadE22, echA1),* cofactor biosynthesis *(moaE*, *moaC2)*, detoxification (*ephA*, *ephF, alkA*), and intermediary metabolism (*epiA, gmdA*) are pseudogenes or deleted in both bacilli (Cole *et al*., 2001a; Garnier *et al*., 2003). Similarly, *M. leprae* and *M. bovis* have lost the AtsA system for recycling sulfate. AtsA is an arylsulfatase that catalyzes the hydrolysis of sulfate esters to release inorganic sulfate. Loss of this function may reflect the lack of sulfated glycolipid in these two mycobacteria. Furthermore, *recBCD* are deleted in *M. leprae*, while *recB* is frameshifted in *M. bovis*.

3.2. *Metabolic insight*

While the genome of *M. tuberculosis* encodes a broad metabolic potential, *M. leprae* appears to have streamlined its genome to the minimum required. This is perhaps best seen in lipid metabolism, where the multiplicity of *fadD*, *fadE*, and *echA* enzymes in *M. tuberculosis* is reduced to 8 *fadD*, 4 *fadE*, and 2 *echA* in *M. leprae*. Of the 8 *fadD*, 4 are of the novel fatty acyl-AMP ligase family (*fadD26*, *fadD28*, *fadD29*, *fadD32*,) and each has their cognate PKS gene intact, indicating the functional linkage of these genes (Trivedi *et al*., 2004). Similarly, while there are 22 putative lipases in *M. tuberculosis*, only 2 are present in *M. leprae*; the consequence of this may be to reduce the spectrum of lipid substrates that can be exploited by the bacillus.

Mycobacterium leprae has lost genes involved in microaerophilic and anaerobic metabolism, such as fumarate reductase and nitrate reductase. This is somewhat surprising in that it is predicted that the in vivo environment is oxygen limited, and may be reflected in the slow growth of the bacillus in the host. Most strikingly, *M. leprae* has deleted the majority of the operon encoding the membrane spanning

NADH oxidase involved in recycling NADH. Hence, the bacillus will be limited both in its capacity to recycle NADH and to generate energy from NADH produced from the TCA cycle. As the ability to recycle NADH is essential, it is possible that enzymes such as malate dehydrogenase, lactate dehydrogenase, or the putative NADH dehydrogenase encoded by ML2061, may function to regenerate NAD.

While catabolic functions have suffered heavily through mutation, the anabolic systems of the bacillus appear replete (Wheeler, 2001). Indeed, the coding commitment to cell wall biosynthesis is very similar to that in *M. tuberculosis*, stressing the complexity of this structure. Surprisingly for an obligate intracellular pathogen, all genes necessary for the biosynthesis of purines and pyrimidines are present. Similarly, the only lesions in amino acid biosynthesis are in the pathway to methionine. This would suggest that the in vivo niche occupied by the organism is nutrient poor, necessitating de novo synthesis. This may also explain the loss of most amino acid permeases. However, it is remarkable in an organism with such extensive streamlining that the asparagine permease is duplicated. Considering that asparagine is the preferred nitrogen source of tubercle bacilli, this may reflect a common metabolic preference.

3.3. Repetitive DNA

The specialized niche occupied by *M. leprae* limits its opportunity for contact with other organisms. Horizontal transfer of genetic material, such as insertion sequences (IS), would therefore be a rare event. This is borne out by the evidence in the genome, where there are 26 transposase pseudogenes but apparently no functional IS. These elements were most likely acquired prior to sequestration of the bacillus in the in vivo niche, with subsequent inactivation by mutation.

Tandem repeats are found in the genome of *M. leprae*, and some of these are proving useful as markers for molecular epidemiological analysis. Matsuoka *et al*. (2004) identified a TTC microsatellite repeat that varied from 8 to 29 copies across *M. leprae* isolates. They used the variability at this locus to show that there were multiple sources of infection in a local village setting, with infected family members showing different genotypes. MIRU minisatellite repeats are also found in *M. leprae*, but a scan of their variability across 14 *M. leprae* isolates from a wide geographical distribution did not reveal any evidence of polymorphism (Cole *et al*., 2001b), contrary to what is seen in *M. tuberculosis* and ruling out their utility as an epidemiological tool.

The genome contains at least 4 families of repetitive DNA contributing approximately 2% to the total genome size (Cole *et al*., 2001b). These sequences are designated RLEP (37 copies), REPLEP (15 copies), LEPREP (8 copies) and LEPRPT (5 copies), and are specific to *M. leprae*. The LEPREP sequence contains pseudogenes with similarity to transposases and the maturases of class II introns, enzymes that catalyze DNA transposition. This suggests a once-functional mechanism for replication of the sequence through the genome. Recombination between repetitive loci appears to have been a central shaper of the *M. leprae* genome. Comparison with *M. tuberculosis* reveals that repetitive elements occupy the junctions of mosaic segments. It is probable that replication, or homologous

recombination, of repetitive elements led to looping out and excision of intervening DNA segments, catalyzed by the once-functional RecBCD complex.

3.4. Failure of axenic culture

The genome sequence does not reveal a specific reason for the inability to culture *M. leprae* axenically. It is most likely that *M. leprae* is so specialized to the host niche that in vitro culture will require a detailed knowledge of the carbon sources and metabolites available to the bacillus in vivo. Moreover, the extensive loss of genes for catabolic functions suggests a limited range of carbon sources would support growth. Metabolic streamlining will also affect the flux of carbon through metabolism, again suggesting that a specific set of carbon substrates will be needed to maintain equilibrium. Computer-aided metabolic reconstruction, with particular reference to energy sources available in vivo, offers one route to the identification of the likely carbon substrates. However, as the doubling rate of *M. leprae* in vivo is 14 days, it would take over 1 year for a colony to form even if in vitro growth was achieved.

4. Conclusions

In contrast to the situation in the 1970/1980s when mycobacterial genetics lagged behind the strides being made in other bacteria, today the mycobacteria represent a genomically well-characterized genus, for which numerous genetic tools exist. Apart from the four published complete genome sequences of *M. tuberculosis*, *M. bovis*, and *M. leprae*, a range of other mycobacterial genome sequencing projects are at different stages of completion, including the vaccine strains BCG and *M. microti*, as well as the fish pathogen *M. marinum*, several strains from the *M. avium-intracellulare* complex, and the environmental organism *M. smegmatis*. (For an overview, see **http://www.pasteur.fr/recherche/unites/Lgmb/Overview-Genome-Projects.html**.) This information provides a knowledge base that is catalyzing research into new disease-control strategies in diagnosis (see Cockle *et al*., 2002), vaccine development (e.g., De Groot and Martin, 2003), and drug-targets (see Smith and Sacchettini, 2003) that are desperately needed to cope with the burden of mycobacterial disease.

Specialist Review

The Mycoplasmas – a congruent path toward minimal life functions

Leka Papazisi and Scott N. Peterson
The Institute for Genomic Research, Rockville, MD, USA

1. The mycoplasma lifestyle

The *Mycoplasmas* are a diverse group of bacteria that arose within the low-G+C gram-positive branch approximately 600 million years ago (Maniloff, 1996; Woese *et al*., 1980). Within this group, genomes range in size between 580 Kb (*M. genitalium*) and 1700 Kb. Despite their ancestral relationship to gram-positive bacteria, *Mycoplasmas* lack a cell wall and the genes encoding cell wall components. Human and animal infections with *Mycoplasmas* appear to affect mostly mucosal tissues in the respiratory and genito-urinary tract, joints, or mammary glands. Generally, infections are not fatal to the host, but instead result in chronic disease sequelae. *Mycoplasmas* have long been considered as surface pathogens, however, more recently, an increasing number of reports suggest an intracellular existence (Lo *et al*., 1989; Lo, 1992; Dallo and Baseman, 2000; Baseman *et al*., 1995; Winner *et al*., 2000; Much *et al*., 2002). It is not yet clear if these invasive *Mycoplasma* species can replicate inside the host cell, but the ability to establish an intracellular lifestyle helps to explain the persistence of *Mycoplasma* infection in the face of host immune response and antibiotic treatment. Readers wishing to learn more about the biology of these bacteria are directed to several excellent reviews (Dybvig and Voelker, 1996, Razin *et al*., 1998, Razin and Herrmann, 2002, Maniloff *et al*., 1992).

As we implement comparative genomic characterization of various bacterial species, it is becoming increasingly clear that bacterial genomes are dynamic and that many genes are more appropriately viewed as being in flux rather than permanent residents. The parasitic lifestyle of the *Mycoplasmas* has allowed the loss of numerous genes encoding proteins representing complete or nearly complete metabolic pathways. *Mycoplasma* genomes are essentially devoid of enzymes involved in the biosynthesis of any amino acids, nucleotides, or lipids. The energy-producing pathways are also minimal. *Mycoplasmas* lack enzymes associated with the tricarboxylic acid cycle and cytochromes. Given the unifying theme of parasitism and the pathway of reductive evolution, it is remarkable that such a diversity

of genomic solutions has arisen for the purpose of energy production. Fermentative *Mycoplasmas* utilize carbohydrates via glycolysis, whereas nonfermentative cells carry out the hydrolysis of arginine. The *Ureaplasmas*, whose favored niche is the urogenital tract, generate 90% of their energy requirements through urea hydrolysis (Smith *et al*., 1993; Razin *et al*., 1998). When one applies clustering analysis to diverse bacterial genomes on the basis of the presence or absence of genes, the resulting clusters group the bacteria bearing minimal genomes together despite their sometimes distant phylogenetic relationships (Hutchison III and Montague, 2002). This result suggests that reductive evolution is, to a large extent, convergent. A comprehensive analysis of the presumed metabolic capacities of the *Mycoplasmas* by Pollack resulted in the identification of a "*Mycoplasma* consensus metabolism" (Pollack, 2002a,b), which, as expected, underscores a "genomic economy". It is likely that as we improve our comparative capabilities, we will see other examples that display the diversity of environmental-specific solutions to common cellular demands. At first glance, it would seem that bacteria have found many ways of achieving fitness that depend on a very large number of genes present on earth.

2. The "minimal cell"

Chromosomal segments within bacterial genomes are both acquired and lost at frequencies far greater than previously appreciated. The rate at which genomes evolve is related, in part, to the type and magnitude of selective pressures the microbe is forced to contend with. Some gene-acquisition events are special in that the inherited genes allow the microbe to occupy a new environment. A new environment generally involves new selective pressures. Therefore, the selective value of each gene in a genome is redefined in accordance with the new environment. Genes possessing a selective value below a particular threshold are likely to be lost from the genome. The transition to an intracellular existence may represent a situation wherein the selective pressures are reduced dramatically, especially for certain types of genes. This mode of genome sampling and clearing of nonadvantageous genes is not unique to the minimal bacteria but rather thought to represent a generalized means of adaptation in the bacterial world. The *Mycoplasmas* have simply taken things to an extreme, because their environment allows them to. It would appear that the uniformity of pathogenic (parasitic) character among the *Mycoplasmas* and a small genome is not coincidental. Some genomes, like those of the *Mycoplasmas*, have come close to achieving an environmentally defined genome minimum. We remain ignorant as to just how close they have come.

A cell bearing a truly minimal genome does not exist in nature, since the formation of such a genome could only occur in an environment that is free of selective pressure. Mushegian and Koonin (1996) were the first to apply a computationally based comparative analysis of completely sequenced microbial genomes as a means of identifying a minimal gene set. Through this analysis, a core set of conserved genes was identified that encodes the basic machinery required for translation, DNA replication, minimal transcription, anaerobic metabolism (glycolysis and substrate level phosphorylation), and a minimal metabolite transport system (Mushegian and

Koonin, 1996). The genomic era has provided impetus for the increase in experimental reports intended to globally identify dispensable genes in genomes, in order to infer which genes are essential (Hutchison *et al*., 1999; Gerdes *et al*., 2003; Kobayashi *et al*., 2003; Ji *et al*., 2001; Jardine *et al*., 2002). Each of these studies defines a similar but distinct set of core functions representing highly conserved genes similar to those defined by the computational approach. It is interesting that each of these studies also identifies a substantial number of essential genes that are lineage specific and poorly conserved over even short phylogenetic distances. For example, the essentiality of the fimbrial gene *fim*A has been speculated to correlate with Zinc transport (Akerley *et al*., 2002). In *Bacillus subtilis*, most genes involved in the Embden–Meyerhof–Parnas pathway (not considered essential) were found to be essential indeed, which led investigators to speculate that besides their (primary) annotated functions, they may play additional roles in this bacterium (Kobayashi *et al*., 2003).

3. Mycoplasma genomes

A wealth of whole-genome sequencing data pertaining to *Mycoplasmas* has allowed many new insights to be made and has furthered our understanding of genome properties common to minimal genomes. The low-G+C nucleotide composition is a signature, not only of Mycoplasma genomes but also of other obligate intracellular pathogens or endo-symbionts. A positive correlation exists between genome size and G+C content in eubacteria. Comparative analysis indicates that genes encoding many DNA repair functions are absent among bacteria with minimal genomes. For example, the gene encoding for uracil *N*-glycosylase (*ung*), an enzyme mediating the removal of uracil from DNA, is absent in some species. Interestingly, those *Mycoplasma* genomes retaining uracil *N*-glycosylase activity possess enzymes with reduced activity, compared to the *Escherichia coli* encoded enzyme (Razin *et al*., 1998; Zou and Dybvig, 2002). The significance of an AT-rich genome and its relationship to minimal genomes is not yet clear, but it has been proposed to be a means of conserving energy (Rocha and Danchin, 2002) and/or a mechanism for evading the innate immunity in multicellular eukaryotes since methylated bacterial CpG strings are known to induce a proinflammatory response via toll-like receptors (Hemmi *et al*., 2000).

Whole-genome sequencing has revealed that genes in many bacterial genomes are encoded asymmetrically on the two DNA strands. Although a precise explanation for this phenomenon remains unclear, the occurrence of extreme gene asymmetry is a characteristic of the low-G+C bacteria (Rocha *et al*., 2000; Rocha, 2002). Comparative analysis of the *M. genitalium* and *M. pneumoniae* genomes suggests that maintenance of strand bias is important and under positive selection (Himmelreich *et al*., 1997). Among the genomic rearrangements that distinguish these genomes, the degree of strand bias remains essentially unaltered. The authors speculated that DNA replication and gene transcription might be coupled. The biased representation of genes on the leading strand may reduce the occurrence of collisions between the DNA replication and RNA transcription machinery. On the basis of computational methods, Rocha and Danchin (2003) concluded that the leading strand is biased in favor of essential genes.

Mycoplasma evolution has resulted in a reduction of noncoding DNA (intergenic) in these genomes (range 8–10%). The average noncoding DNA in low-G+C gram-positive and other prokaryotic genomes is higher (15% and 13% respectively) (Rogozin *et al*., 2002). By contrast, the average gene length in *Mycoplasma* genomes is larger when comparing orthologous genes from other bacteria (Wong and Houry, 2004; Oliver and Marin, 1996; Skovgaard *et al*., 2001). Oliver and Marin (1996) observed a correlation between the average gene length and a genome's G+C composition. It is known that the average length of conserved genes is longer than nonconserved genes (Lipman *et al*., 2002). While it is true that *Mycoplasma* genomes contain a larger portion of conserved genes and this may thereby account for the observed gene length increase, it may also highlight gene fusion events, wherein variable portions of two coding sequences merge into one, with expanded functional capacity. Two-thirds of the *M. genitalium* gene products are predicted to contain at least two domains (Teichmann *et al*., 1998; Teichmann *et al*., 2001). Putative intraoperonic spacers (distance between two unidirectional gene pairs) are the lowest among all bacteria in Mycoplasma genomes (Fukuda *et al*., 1999; Rogozin *et al*., 2002). Using the method of Ermolaeva *et al*. (2001), we found that the number of genes in presumed operons is higher in *Mycoplasmas* compared to other gram positive bacteria or obligatory intracellular pathogens (Buchnera omitted).

4. Repetitive DNA

The occurrence of repetitive DNA is conserved among the *Mycoplasmas* and constitutes a surprisingly high percentage of their genomes, ranging from 4.2% in *M. genitalium* to 28% in *M. mycoides*. *Mycoplasmas* are rich in both large and short repetitive elements. Large repeats consist mostly of insertion sequences, pseudogenes, and paralogous gene families, generally encoding membrane proteins. It is common for individual members of paralogous gene families to exhibit length polymorphisms in the encoded proteins. Their role as a reservoir of DNA for generating antigenic variation and/or epitope masking has been well documented (Razin *et al*., 1998; Rosengarten *et al*., 2001). Short repeats are found both in coding and noncoding sequences. In addition to their presence within genes encoding surface proteins, short repeats are frequently found within genes whose products participate in recombination, repair, and transcription. Karlin *et al*. (1997) and Rocha and Blanchard (2002) examined the frequency and location of short repeats within coding DNA sequences and provided novel insights into the role of these repeats on species fitness and evolution. Repetitive DNA in *Mycoplasma* genomes exhibits the same strong propensity to be oriented in the same localized direction as neighboring transcription units, suggesting that insertion of such elements in the opposite polarity are poorly tolerated.

5. Transcription in the mycoplasmas

Detailed information pertaining to transcription and its regulation in the *Mycoplasmas* is somewhat limited, however, some themes appear to be emerging. The

core structure of *Mycoplasma* promoters resembles those from other eubacteria and is composed of both −10 and −35 regions. The Pribnow Box (−10 region) sequence has been found to be conserved, whereas the −35 region appears more divergent (Weiner *et al*., 2000; Muto and Ushida, 2002). Other cis-acting regulatory sequences have not been reported and appear refractory to identification. An exception to this is that some *Mycoplasma* genomes contain CIRCE-like elements upstream of several heat-shock genes.

The *vlh*A gene family in *M. gallisepticum* encodes surface lipoprotein hemagglutinins. The expression of *vlh*A genes is controlled by a simple repeat sequence (GAA) located in upstream promoter regions (Markham *et al*., 1993; Glew *et al*., 1995; Glew *et al*., 2000). Alterations in the copy number of this tri-nucleotide repeat result in gene expression changes that reach a maximum when the repeat number is 12. In *M. hyorhinins*, the sequence between the −10 and −35 promoter region of variable lipoprotein (*vlp*) family genes contains of a polyA tract. Contraction and expansion of this spacer region alters promoter topology, thus affecting the efficiency of transcription of downstream genes (Citti and Wise, 1995). It is noteworthy that both of these examples involve the regulation of genes known to contribute to establishing antigenic variation (Baumberg *et al*., 1995). Antigenic variation is advantageous but the selection acts at the level of the population, not the cell, since the genotypic changes giving rise to antigenic variation occur at a very low frequency.

Transcription termination and its regulation are poorly understood in the *Mycoplasmas*. The gene encoding the terminator protein Rho is absent in the *Mycoplasmas*. Short inverted repeats following a gene, whether they fit a consensus terminator motif or not, are indicative of a potentially energetically favorable RNA hairpin loop formation capable of facilitating transcription termination. Neither *M. pneumoniae* nor *M. genitalium* appears to rely on hairpin formation for transcription termination, since such sequences are not present downstream of coding sequences at any appreciable frequency (Washio *et al*., 1998). The genes encoding the transcription termination factors, NusA, NusB, NusG, or GreA, are found alone or in various combinations among *Mycoplasma* genomes. These proteins are known to be involved in RNA transcript termination, antitermination, and/or attenuation.

All *Mycoplasmas* possess the gene encoding the vegetative sigma factor (σ^{70}) but appear devoid of genes encoding alternative sigma factors. The *Mycoplasmas* are essentially devoid of genes encoding cellular signal transduction (two-component regulators). One known exception to this lies in the genome of *M. penetrans*, which does possess such regulators (Sasaki *et al*., 2002). Protein sequence motifs commonly found in DNA binding and regulatory proteins are absent in some Mycoplasmas such as *M. genitalium,* and are otherwise scarce throughout this bacterial group (Table 1) (Razin *et al*.).

The lack of alternative sigma factors, and/or recognizable transcription factors in *M. genitalium*, is consistent with our experimental findings using DNA microarrays to monitor global gene expression. We have failed to identify any RNA abundance alteration for any gene in response to either serum starvation or nutrient deprivation, which entailed a comparison of transcript abundance in cells growing in mid-logarithmic growth to cells in stationary and late stationary phase growth. Recently,

Table 1 Frequency of selected Prosite motifs per unit (1 Mb) genome among various prokaryotes found through PEDANT

Motifs	"Pneumoniae clade" ($n = 5$)	All Mycoplasmas ($n = 8$)	Symbionts ($n = 3$)	Intracellular pathogens ($n = 3$)	Gram positives ($n = 10$)	Gram negatives ($n = 8$)	Other free-living bacteria ($n = 3$)	Prokaryotes other than *Mycoplasmas* ($n = 27$)

an investigation of the *M. pneumoniae* transcriptional response to cold- and heat-shock by microarray analysis indicated that gene expression changes greater than twofold were not detected (Weiner *et al*., 2000).

It remains unclear whether transcriptional regulation and termination in the *Mycoplasmas* occurs through a novel mechanism, or whether their reduced repertoire of genes devoted to this function represents a minimal solution to regulating transcription. It is conceivable that as a genome approaches a minimum size and the fraction of genes encoding essential functions gets sufficiently high, the organism may benefit from dispensing with or relaxing transcriptional regulation. Although the experimental evidence is still limited, protein-level analysis and predictive computational analyses suggest that posttranslational modification occurs routinely. Wasinger *et al*. (2000) investigated the *M. genitalium* proteome during exponential and stationary phase growth and revealed a substantial, but not unusually high, occurrence of posttranslationally modified proteins. The abundance of proteins correlated with codon adaptation indices to a large extent (Wasinger *et al*., 2000). It has been established by Krebes *et al*. (1995) that one of the HMW proteins that plays a role in the formation of the cytadherence organelle undergoes phosphorylation. In *M. gallisepticum* and *M. fermentans*, another form of regulation involving differential cleavage of membrane proteins has been documented (Davis and Wise, 2002; Gorton and Geary, 1997). Specific proteolytic cleavage of cytadherence-related proteins in various *Mycoplasma* species such as *M. pneumoniae, M. hyopneumoniae*, and *M. gallisepticum* is known to occur (Layh-Schmitt and Harkenthal, 1999; Djordjevic *et al*., 2004; Steven J. Geary, University of Connecticut, US, personal communication).

The genes encoding the highly conserved chaperones such as the GroEL/GroES proteins involved in intermediate protein folding are found sporadically in *Mycoplasma* genomes. It has been speculated that a broadened functional capability of early step folding carried out by proteins such as Tig and DnaK, or by the proteases Clp and/or Lon may compensate for this genomic loss (Wong and Houry, 2004). For reasons that are not yet clear, *Mycoplasmas* have established a fundamental shift toward processes featuring protein processing (proteolysis, chaperonins, modification, degradation) as a primary means of protein-level regulation. In support of this model, we find an inverse correlation between the frequency of the helix-turn/loop-helix and chaperones or protease motifs per unit length of genomic DNA (Table 1).

6. A reductive evolution model: The loss of transcriptional regulators

Bacterial genes are typically regulated at the level of transcription by both positive (activators) and negative (repressors) regulators. In general, these regulators function through interaction with specific regulatory sequences within promoters. It is interesting to consider the consequences of losing a gene encoding for a transcriptional activator. The immediate impact to the regulator's target genes is clear. Transcription of target genes may either be dampened or extinguished

completely. The complete loss of expression of target genes can only be tolerated if the genes in question encode dispensable functions, and their loss in subsequent genomic reductions will also be tolerated. There are genes within all genomes, like the highly conserved gene, *rec*A, that while dispensable, provide selective value to the cell and its overall fitness. When genes of this type fail to be expressed, the cell is under greater pressure to find alternative means of reestablishing their expression. Given what we know about *M. genitalium* gene expression, it is possible that the cell was able to exploit its genomic "weakness" regarding poor recognition of transcriptional termination and turn it into an advantageous phenotype. Essential genes or dispensable genes of selective value, left with no means for expression, may be rescued by transcriptional read-through of termination signals from neighboring genes (Figure 1).

One model pertaining to genome evolution, referred to as the "selfish operon" model, starts by assuming that horizontal acquisition of chromosomal segments has been common during bacterial evolution (Lawrence and Roth, 1996). According to the selfish operon model, the inheritance of novel, advantageous, multigenic traits is more probable if all required genes can be acquired in a single DNA transfer event. Most genes within horizontally acquired DNA provide no selective advantage to the host and are lost over time. The sequential loss of useless DNA serves to increase the physical linkage of coselected genes. The increased physical linkage between coselected genes, in turn, increases the probability that they will be coacquired in

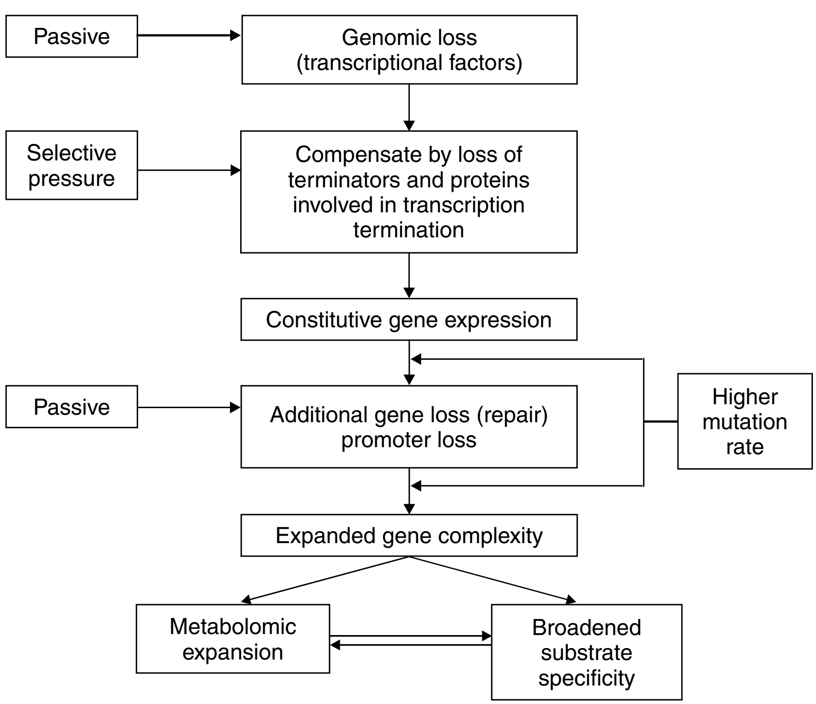

Figure 1 Reductive evolution model

a single event, and so on. Theoretically, this self-perpetuating process reaches an end point when coselected genes achieve maximal linkage (a coregulated operon). The fact that bacterial operons contain "like-minded" genes with respect to their function is a natural consequence of the fact they were coselected through a process of reductive evolution.

The scenario described above with regard to the loss of a transcriptional activator contains several intriguing analogies to the selfish operon model. First, the rescue of advantageous genes with no means of expression by read-through transcription also depends on the physical linkage of selectively advantageous genes to active promoters. Deletions that minimize the distance and boundaries separating transcription units containing essential genes may be under strong positive selection. Like the selfish operon model, a ratcheting effect is also implicit. As the selective pressure to reduce the efficiency of transcriptional terminator recognition is successfully accomplished, through the loss of proteins such as Rho, the probability is that subsequent loss of transcriptional regulators controlling essential genes will be tolerated. As regulators are lost, the cell becomes progressively more dependent on constitutive promoters. It is clear that the *Mycoplasmas* have become highly dependent on σ^{70}. If correct, this model implies that the loss of efficient transcriptional termination was perhaps a crucial step that enabled the substantial reductive evolution of the *Mycoplasmas.* By contrast to the selfish operon model, the forces acting to drive genome reduction act at short distances, perhaps limited by the processivity of RNA polymerases. The extant *M. genitalium* genome and its unique features support the basic tenants of this model, however, without specific knowledge of the temporal order of loss in this minimal genome, it is difficult to establish stronger support for this model of reductive evolution. We are currently pursuing experimental validation of various aspects of this model.

Visual inspection of the gene organization of the *M. genitalium* genome, while difficult to quantify, suggests that it is reminiscent of a viral genome. The asymmetry of gene orientation to be consistent with the direction of DNA replication is extreme and accounts for nearly 85% of the annotated genes. Operons are conspicuously long and compactly organized, with genes often overlapping by a few nucleotides. There are 35 regions on the chromosome-harboring genes oriented counter to the majority. This means that there are 35 places in the genome where neighboring genes are oriented in a head-to-head arrangement (3′ end to 3′ end). In 25 of these regions (Figure 2), the break point between properly oriented and misoriented regions is defined by a perfect head-to-head arrangement (little or no intervening sequence). At the opposite end of the region, we observe more heterogeneity in structure, suggesting that sequences upstream of genes are less able to adopt such compactness. Among the 10 cases (of 35) where perfect head-to-head gene arrangement do not exist, the break point in four of these lie immediately upstream of tRNAs or adhesin gene repetitive DNA. The remainder are flanked by rare voids in the annotated genome. These voids may represent genes undergoing decay and are perhaps destined to be lost from the genome. The tight packaging of genes in operons together with the differential behavior or 5′ and 3′ noncoding regions, the latter being more susceptible to removal of all intergenic sequence, may reflect an active mechanism used to vigilantly remove DNA sequences lacking functional significance.

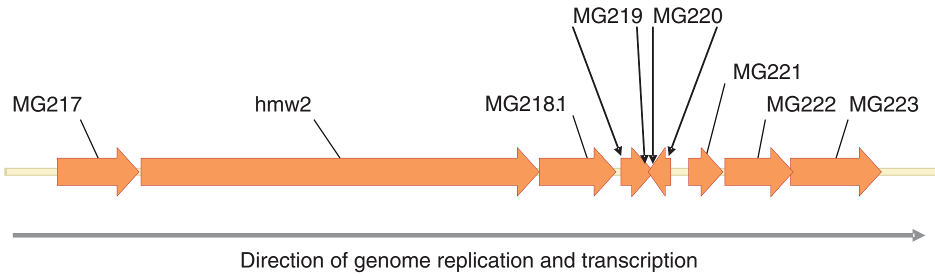

Figure 2 MG220 is in a nonmajority orientation. Arrows indicate perfect head-to-head arrangement of MG219 and MG220, and the more variable tail-to-tail arrangement of MG220 and MG221

7. Coping with a minimal genome

Genome reduction in the *Mycoplasmas* has generated a streamlined recombination and repair system. The lack of many DNA repair functions undoubtedly contributes to the high mutation rate observed in *Mycoplasma* genomes. *Mycoplasma* gene mutation rate is the highest among the prokaryotes and may be as high as 10^{-2} to 10^{-4} per generation (Razin *et al*., 1998; Ochman *et al*., 1999). This high mutation rate is significant and not necessarily a bad phenotype for a minimal cell to possess. It would be reasonable to assume that the Mycoplasmas were able to compensate for the loss of various biosynthetic capabilities through a modest expansion of their transporter repertoire. It has been reported that the number of transporters encoded by a bacterium is proportional to genome size. Mycoplasma genomes do not represent an exception (Fraser *et al*., 2000). While the number of proteins predicted to be involved in transport is relatively limited, *Mycoplasmas* may have alternatively evolved transport systems with broadened substrate specificity (Razin *et al*., 1998; Fraser *et al*., 2000; Maniloff, 1996; Saurin and Dassa, 1996). *Mycoplasma* transporter sequences show a significant divergence compared to orthologs in closely related genomes.

Similar evolution has been noted among metabolic enzymes. Cordwell *et al*. (1997) reported the unique activity of *M. genitalium* lactate dehydrogenase (LDH). Their analysis indicated that this 2-ketoacid dehydrogenase class enzyme may also confer malate dehydrogenase (MDH) activity. *Mycoplasmas* lack nucleoside phosphate transport. In this case, a solution relying on membrane-bound broad-affinity enzymes with 5′-nucleotidase activity that converts nontransportable nucleotides into transportable nucleosides (Pollack, 2002b). Purine nucleoside phosphorylase (PNP) has been shown to have equal activity for nucleobases and nucleosides (McElwain *et al*., 1988). The "patchwork" model of metabolic evolution suggests that the evolution of metabolic pathway has been driven by the expansion or alteration of enzyme substrate specificity. In other words, the novel preexisting enzymes with extended substrate specificity may be recruited to perform the same chemical conversions on a larger number of substrates (Jensen, 1976; Lazcano and Miller, 1999; Copley, 2000). It is interesting in this regard that the *M. pneumoniae* genome contains numerous tandem arrays of genes that define small paralogous families. As mentioned previously, these duplicated genes display

substantial length and sequence polymorphisms. It may well be that it is through mechanisms like these that such broadened substrate specificity is achieved.

The path of genomic minimalism undertaken by the *Mycoplasmas* comes with the price of driving the species evolution toward niche speciation. In this regard, *Mycoplasmas* rarely cross (phylogenetically distant) host species (Razin *et al*., 1998; Peterson and Fraser, 2001; Himmelreich *et al*., 1997). Reductive evolution represents one path among potentially countless others. It is possible that by gaining further insights into the forces causing reductive evolution and the mechanisms acting to achieve a minimal genome, we will be provided insights into a general mechanism that has acted in all bacterial genomes to continually ensure that genes of selective value are maintained and those that do not are lost. If genome evolution is in fact driven by horizontal transfer and acquisition of novel genes and functional capabilities, it seems likely that bacteria have developed efficient mechanisms for processing useless DNA for removal. It may be that the future evolutionary fate of the *Mycoplasmas* in this regard is not entirely in their own hands but, like that of any obligate intracellular pathogen, inextricably linked to the evolutionary fate of their hosts. On the other hand, we should not be too quick to underestimate the resourcefulness of the minimalist bacteria, as they do seem more than capable of finding ways to manage, even with a reduced set of tools at their disposal.

Specialist Review

The nuclear genome of apicomplexan parasites

James W. Ajioka and Elizabeth T. Brooke-Powell
University of Cambridge, Cambridge, UK

Universiti Kebangsaan Malaysia, Bangi, Selangor DE, Malaysia

1. Introduction and background

The phylum Apicomplexa represents a unique opportunity to explore how evolution and natural selection have generated what is arguably the most successful and important group of eukaryotic parasitic pathogens, accounting for morbidity and mortality figures in the hundreds of millions per annum. The phylum consists of a highly diverse group of unicellular organisms that are obligate intracellular parasites of metazoans. It is represented by about 4600 described species, with the possibility of an order of magnitude more remaining undiscovered (Ellis *et al*., 1998). The current lack of complete molecular data for representative members of the Apicomplexa preclude a detailed and reliable phylogenetic reconstruction within the phylum, but recent studies indicate that distinct lineages will emerge (see for example Leander *et al*., 2003; Aravind *et al*., 2003). Although particular lineage rankings and relationships are currently the subject of some debate, the molecular data are generally consistent with the traditional taxonomic classifications based on morphology and life cycles such that the relationships between species of medical and veterinary importance are sufficiently robust for most comparative purposes (see Table 3).

The defining characteristic of the Apicomplexa, the "apical complex", is found on the parasites' asexual forms and mediates attachment and invasion of host cells. It consists of microtubule-based features known as the conoid, polar rings, and subpellicular microtubules. Through this structure, the associated secretory organelles known as the rhoptries and micronemes are able to release their contents (Blackman and Bannister, 2001; Dubey *et al*., 1998). Other features likely to be shared by most of the phylum members are a single mitochondrion and the plastid-like organelle known as the "apicoplast", acquired via a secondary endosymbiotic event between a eukaryotic cell and a photosynthetic algae (known exceptions are *Cryptosporida* spp.; Zhu *et al*., 2000; Abrahamsen *et al*., 2004), leaving a single nucleus as the sole chromosomal compartment.

The apicomplexan nuclear genome is a mosaic likely consisting of nuclear genes from both secondary endosymbionts, genes originating from the mitochondrial genome and from the apicoplast genome. Several representative species within the phylum have (nuclear) genomic sequencing and related projects completed or under way, so comparative genetics, genomics, and downstream methods should provide a wealth of information toward both a basic biological understanding of these organisms and ways to combat the diseases they cause (see Tables 1 and 2). Since the representative species are quite distantly related compared to mammalian model organisms, a thoughtful notion of homology is the primary caveat emptor for using these data and guiding the interplay between computational and experimental studies (see, for example, Barta, 1997).

Although the sexual cycle defines the primary host (and hence the range of potential secondary host(s)), asexual reproduction of apicomplexan parasites is the main contributor to human and animal disease. The life cycle of a particular apicomplexan may involve a wide variety of hosts, but sexual reproduction is restricted to a single vertebrate species/species group and cognate arthropod host as appropriate (see Table 3, Figure 1). Apicomplexans exist as nominally haploid (N) cells for the vast majority of their life cycle and bona fide diploid (2N) cells are only associated with sexual reproduction (see Figure 1). Diploid zygote formation followed by a conventional meiosis and sporozoite formation has been established in *Plasmodium* spp., *Eimeria* spp., and *Toxoplasma gondii* (Walliker *et al*., 1976; Walliker *et al*., 1975; Pfefferkorn and Pfefferkorn, 1980; Jeffers, 1976), and is therefore inferred for the other species in the phylum.

Shared (and likely homologous) processes such as schizogony, a process by which several rounds of nuclear and organellar replication occur before the re-formation of individual parasite cells, and gamete formation may be most easily studied in a particular species. So, comparative inference will be a powerful tool for understanding these fundamental properties across the phylum. The control of asexual reproduction appears to be critical for parasite development/differentiation, where basic properties of the cell cycle may be common features in developmental decisions as disparate as gametogenesis, sporogenesis, and tissue cyst formation. Gametogenesis in *Plasmodium* spp. may be linked to the control of asexual replication as it has been viewed as “opting out” of the cell cycle (Dyer and Day, 2000). *Eimeria* spp. produce large schizonts with a set number of asexual replication cycles prior to the onset of the sexual cycle and sporogeny (see, for example, McDonald and Rose, 1987; McDonald and Shirley, 1987). Infection with *T. gondii* sporozoites results in a transformation to tachyzoites that have a limit of about 20 asexual divisions before they develop into the cyst form bradyzoites (Jerome *et al*., 1998). A detailed analysis of asexual reproduction and cell cycle control will likely shed considerable light on mechanisms of development in apicomplexans.

2. Nuclear genomes and genetics

Defining the sexual cycle in the apicomplexans has allowed genetic linkage analysis of the nuclear genome, underpinned population genetic studies, and provides a foundation for genomic analysis (see Tables 1 and 2). The development of genetic

Table 3 Comparative life cycles

Subclass (suborder)	Genus	Meiosis & sporulation	Host tissue/ cell infected	Asexual tissue cycle	Trophozoite & schizont/ merozoite cycle	Gametogenesis	Microgamete exflagella-tion	Gametic fusion/ zygote formation
Coccidia (Haemospo-rina)	*Plasmodium*	Mosquito gut wall	Human hepatocyte, erythrocyte	None	Human hepatocyte, erythrocyte	Human erythrocyte	Mosquito gut	Mosquito gut
Coccidia (Eimeriina)	*Eimeria*	Avian feces environment	Avian gut epithelia	None	Avian gut epithelia	Avian gut epithelia	Avian gut	Avian gut epithelia
Coccida (Eimeriina)	*Toxoplasma*	Cat feces environment	Cat gut epithelia	Any nucleated cell; cat or secondary host	Cat gut epithelia	Cat gut epithelia	Cat gut	Cat gut epithelia
Coccida (Eimeriina)[a]	*Cryptosporidia*	Mammalian gut epithelia cell membrane	Mammalian gut epithelia cell membrane	None	Mammalian gut epithelia	Mammalian gut lumen	None	Mammalian gut lumen
Piroplasmia	*Theileria*	Tick salivary gland	Mammalian lymphocyte	None	Macroschizonts make infected lymphocytes divide and ultimately become microschizonts; no merozoite reinfection of new cells	Products of microschizonts invade mammalian erythrocytes	Tick gut lumen	Tick gut lumen

[a]Recent phylogenetic analyses suggest that *Cryptosporidia* may be a deep branching lineage and not a Coccidian (see, for example, Leander *et al*., 2003).

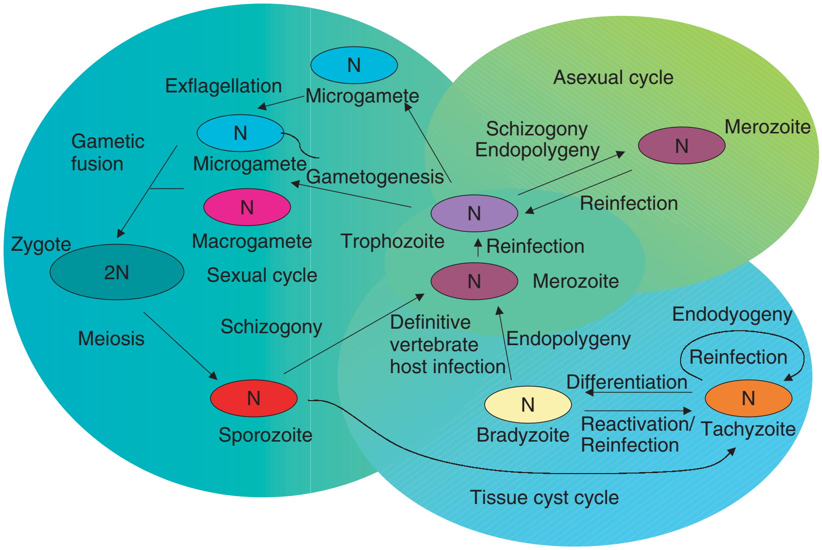

Figure 1 Apicomplexan reproduction. Modes of Apicomplexan reproduction vary, but all known species maintain the sexual and asexual cycles with tissue cyst cycle confined to *T. gondii* and its close relatives. The sexual cycle determines the definitive vertebrate host. Sporozoites infect the definitive vertebrate host, replicate via schizogony. In Coccidians, the newly formed merozoites reinfect host cells and enter the asexual cycle, continuing to amplify in numbers via schizogony/reinfection cycle. In contrast, *Theileria* spp. schizogony do not use host cell lysis/reinfection for amplification, but stimulate infected lymphocyte cell division to increase the number of host cells within which to replicate. In a species-specific manner, after several rounds of asexual reproduction, a proportion of the resulting merozoites go through gametogenesis to form micro- and macrogametocytes. In *Plasmodium* spp. the gametocytes are taken up by the mosquito in a blood meal from the mammalian host. *Theileria* spp. require the products of the schizont to infect erythrocytes to facilitate gametogenesis. The gametes may undergo further changes such as exflagellation of microgametocytes before zygote formation, meiosis, and sporulation. In *Cryptosporidium* spp., exflagellation does not occur but rather the differentiated microgamont goes directly into zygote formation. A small number of Coccidians use tissue cyst formation to exploit carnivorous consumption of bradyzoites for reinfection of the definitive host, and *T. gondii* further uses this mechanism to escape sexual reproduction altogether by transmission between secondary hosts. N refers to haploidy and 2N refers to diploidy

markers has allowed investigations into the inheritance of important disease-related phenotypes such as drug resistance and virulence traits. These genetic markers have also supported studies to understand the population structure and geographical distribution of virulence-associated alleles.

2.1. *Plasmodium spp*

Plasmodium spp. life cycle requires both a primary vertebrate host and a mosquito vector. The major mode of asexual reproduction, schizogony, occurs first in vertebrate host hepatocytes and then in erythrocytes. The sexual phase begins with gametogenesis in the vertebrate host followed by uptake by the mosquito, where zygote formation, meiosis, and the generation of infective sporozoites occur (see Figure 1).

Although the primary focus of plasmodium genetics has been the human malarial parasite *Plasmodium falciparum*, the first demonstrations of genetic recombination were crosses in the rodent species *P. yoelli* and *P. chaubaudi* (Walliker *et al*., 1971; Walliker *et al*., 1975; Walliker *et al*., 1976). Deliberate mixtures of genetically marked clones fed to mosquitoes revealed inheritance patterns consistent with a conventional chromosomal meiosis in the nuclear genome. The proportions of progeny, those from parental selfing and cross-fertilization, were within Hardy–Weinberg expectations.

The development of genetic markers and analysis of crosses has been used to investigate *P. falciparum* virulence-related traits such as cytoadherance, host cell invasion, transmission (Walliker *et al*., 1987; Vaidya *et al*., 1995; Guinet *et al*., 1996; Day *et al*., 1993; Wellems *et al*., 1987), and drug resistance as both heritable phenotypes and as a tool to track resistance phenotypes geographically (Peterson *et al*., 1988; Wellems *et al*., 1990; Cowman and Karcz, 1993; Goldberg *et al*., 1997; Su *et al*., 1997). Since *P. falciparum* genetic crosses are difficult and generally have been used in multiple studies, one such cross between HB3 and Dd2 parents was extended and used to produce a genetic map, defining recombination parameters (Su *et al*., 1999). Thirty-five progeny were analyzed with 901 RFLP and microsatellite markers showing 14 linkage groups totaling 1556 centimorgans (cM). The average length of the 326 mapped segments is estimated to be about 80 kb, giving an average map unit size of 17 kb per cM. Moreover, this figure varies little across and between chromosomes, indicating that the crossing-over frequency is not only relatively high, but uniform as well. However, a separate analysis of this cross indicated that the subtelomeric *var* genes showed a higher than expected recombination frequency due to gene conversion events between heterologous chromosomes (Freitas-Junior *et al*., 2000). This result provides a mechanism that explains the high diversity within the *var* gene family. Most of the markers showed approximately equal numbers of parental alleles but a few linkage groups displayed uniparental bias. Linkage groups on chromosome 2 and terminal regions of chromosomes 9 and 13 showed excess Dd2 markers compared to linkage groups on chromosomes 3 and 8 that maintained an HB3 bias (see **http://www.ncbi.nlm.nih.gov/projects/Malaria/Mapsmarkers/PfSegData/segdata.html**). Overall, the underlying mechanisms responsible for inheritance bias are unclear but, the *var* gene conversion/recombination events can produce inheritance bias, as evidenced by 10 of 13 progeny inheriting HB3var10-1 via biased gene conversion onto chromosome 9 (Freitas-Junior *et al*., 2000). Uniparental bias in inheritance of organelles is also evident from the previous studies of HB3xDd2 recombinant progeny that showed that the Dd2 parent did not form microgametocytes efficiently (Vaidya *et al*., 1993). The excess of Dd2 macrogametocytes (hence cytoplasm and organelles) resulted in recombinant progeny with exclusively Dd2 cytoplasm and organelles. Bias in cytoplasmic inheritance was also observed in an HD3x3D7 cross, but bias in gametocyte production could not explain this result, so unidirectional gametocyte incompatibility was raised as an explanation (Vaidya *et al*., 1993). Although the sexual cycle is obligatory in *Plasmodium* spp., selfing probably occurs most often, so investigations into both recombination and cytoplasmic inheritance biases may reveal genetic incompatibilities that reflect natural

selection for particular combinations of alleles and organelles, as well as elucidating mechanisms underlying biased gene conversion in terminal chromosomal regions.

The genomic sequence is effectively complete for *P. falciparum* (clone 3D7) and *P. yoelli* (17XNL clone) (Gardner *et al*., 2002; Carlton *et al*., 2002). For *P. falciparum* 3D7, sequence from chromosomal shotgun and selected yeast artificial chromosome genomic clones were assembled, and sequence tag sites, microsatellite markers, HAPPY mapping, and optical restriction maps were used to place, join, orient, and confirm contigs. Within the Apicomplexa, *Plasmodium* species are highly represented in genomic sequencing efforts (see Table 2), and some excellent comparative analyses have been published (see for example, (Aravind *et al*., 2003)). Consistent with the genetic map, the nuclear genome consists of 22.9 Mb distributed across 14 chromosomes ranging in size from about 0.7 to 3.4 Mb. The overall A+T content is just over 80% where regions with lower A+T content generally mark protein-coding sequences. Despite a genome nearly twice the size of the fission yeast *Schizosaccharomyces pombe*, a similar number of genes (~5300) and proportion of genes containing introns (54%) were identified. The average coding sequence length is 2.6 kb, which is larger than that of other unicellular organisms. A recent analysis of *P. falciparum* genes showed that this is partly explained by enrichment with stretches that encode low-complexity regions composed of homopolymeric runs of 10 to >100 asparagine residues, generally between predicted globular domains (Aravind *et al*., 2003). An analysis of GTPases with known structure showed that the insertion of the homopolymeric runs mapped to loops between secondary structural elements and distant from functional P-loop and Walker B domains. The function of the low-complexity inserts remains unclear considering their size, frequency, and interspecific differences. However, their presence in several species of *Plasmodium* suggests that they may be maintained by natural selection, raising the intriguing possibility that common cross-reactive epitopes such as asparagine-rich peptides may impair a useful host immunological response (Anders *et al*., 1986; Aravind *et al*., 2003).

Following the completion of the *P. falciparum* genome, microarray analysis has come to complement classical cloning and sequence comparison studies for the analysis of gene expression. Initial studies focused on expression changes throughout the life cycle of *P. falciparum* (Bozdech *et al*., 2003; Le Roch *et al*., 2003). Asexual intraerythrocytic development of *P. falciparum* monitored over 46 time points showed that approximately 60% of the genome is transcriptionally active during schizogony (Bozdech *et al*., 2003). Transcription appears to be on an "as-needed" basis, gradually changing over time as shown by the peak in expression of all factors associated with DNA replication and synthesis around 30 h, early schizogony. This peak coincides with the transition out of the ring stage, a low point of gene expression, and the initiation of concerted replication of the genome (Bozdech *et al*., 2003).

2.2. *Toxoplasma gondii*

T. gondii has the most promiscuous life cycle of the major disease-causing apicomplexans. Along with the sexual and asexual cycles, *T. gondii* can replicate

in virtually any nucleated cell from any warm-blooded animal and form tissue cysts that can be passed between secondary hosts via carnivory (Hill and Dubey, 2002; see Figure 1). *T. gondii* and its close relatives usually enter the sexual cycle via consumption of encysted bradyzoites and require asexual reproduction via a specialized schizogony called *endopolygeny*. The tissue cyst cycle, unique to *T. gondii* and its close relatives, can be initiated by the ingestion of either a sporozoite or bradyzoite cyst. These parasites reactivate into the rapidly dividing tachyzoite form for further reinfection to virtually any cell type. Tachyzoites multiply via a binary dividing process known as *endodyogeny*, generating large numbers of parasites, and causing acute disease through cellular destruction and host inflammatory response. Asymptomatic chronic infection follows by the differentiation of tachyzoites into bradyzoites that form a tissue cyst that may remain indefinitely in host tissue (Dubey *et al*., 1998).

Several lines of evidence suggest that the cell cycle of these various asexual reproductive forms differ from yeast and mammalian cells. Cell cycle analysis of asexual replication of synchronized *T. gondii* tachyzoites showed that G1 (vast majority of cells = N) occupies about 60% of the cell cycle where the nuclear DNA replication (S-phase) is biphasic (minor fraction of cells in early $S = 1 - 1.7N$; major fraction of cells late $S = 1.8N$) and accounts for about 30% of the cell cycle (Radke *et al*., 2001). S-phase is quickly followed by mitosis such that G2 is very short or nonexistent. Moreover, in stained *P. falciparum* and *Theileria* nuclei in schizogony, a similarly short/nonexistent G2 may be inferred by the lack of 2N nuclei (Irvin *et al*., 1982; Jacobberger *et al*., 1992). It is speculated that the relatively lengthy late S-phase may replace G2 as a premitotic checkpoint for replication in apicomplexans (Radke *et al*., 2001).

The genetic linkage analysis of *T. gondii* represents the most systematic attempt amongst apicomplexan species to develop a genetic map as a general framework for understanding the inheritance of virulence-related phenotypes and for positional cloning of candidate loci. After showing that drug resistance markers on two independent strains of *T. gondii* segregate with Mendelian inheritance in a genetic cross (Pfefferkorn and Pfefferkorn, 1980), a similar cross was used to generate a genetic map using randomly generated restriction fragment length polymorphic markers (RFLP; Sibley *et al*., 1992). Recent refined genetic mapping, in combination with physical mapping/genomic sequencing, extends the number of chromosomes to a total of 13–14 varying in size from 1.8 to 7.4 Mb (D. Sibley, personal communication; **http://toxomap.wustl.edu**).

In contrast to *Plasmodium* spp., the sexual cycle is not obligatory, a property unique to *T. gondii*, which allows asexual reproduction through a tissue cyst/carnivorous cycle between secondary hosts (see Figure 1). This property may explain why studies on the population structure of *T. gondii* show that there are three main clonal lineages (Sibley and Boothroyd, 1992b; Howe and Sibley, 1995) into which the great majority of isolates can be placed (Su *et al*., 2003). These lineages are closely related and appear to be progeny from a single genetic cross (Grigg *et al*., 2001). The vast majority of single nucleotide polymorphisms (SNP) can be classified as one of two parental alleles where all of the isolates within a clonal lineage will share the same allele at every SNP position. The remaining SNPs are so rare that an analysis of neutral SNPs (e.g., those found in introns) suggests

that a rapid global expansion of *T. gondii* occurred very recently, probably within the last 10 000 years (Su *et al*., 2003). Although the clonal lineages are very closely related, there are phenotypic differences including virulence in the mouse model and the ability to form tissue cysts (Sibley and Boothroyd, 1992b; Hill and Dubey, 2002). A cross between the virulent Type I GT-1 ($FUDR^R$; murine $LD_{100} = 1$) and the nonvirulent Type III CTG ($AraA^R$, SNF^R; murine $LD_{100} = 10^4$) strains revealed a major locus for murine virulence on chromosome VII and a minor locus on chromosome IV (Su *et al*., 2002). The genomic sequence assembly across these regions should facilitate the identification of candidate loci for the murine virulence phenotype.

In contrast to the relatively compact A+T-rich *Plasmodium* genomes, the *T. gondii* genome is currently estimated to be 65 Mb and 53% G+C (I. Paulsen, M. Berriman, D. Roos, and J. Ajioka, personal observation). The difference in genome size may be partly explained by more repetitive DNA, an increased number and size of introns combined with a somewhat lower gene density. Of these possibilities, only repetitive DNA has been systematically studied. The gene(s) encoding the B1 antigen are arranged as a single tandem array of 35 elements (Burg *et al*., 1988; Burg *et al*., 1989). Dispersed repetitive elements include the mitochondria-like REP family (Ossorio *et al*., 1991), simple 2–6 nucleotide microsatellite repeats (Ajzenberg *et al*., 2002; Blackston *et al*., 2001), and repeats that are likely to be subtelomeric as represented in the ABTg collection (Matrajt *et al*., 1999). What appear to be bona fide telomere repeats, sharing the same sequence motif with *Plasmodium* spp. and *Eimeria* spp., TTTAGGG, have also been identified (M. Berriman and J. Ajioka, personal observation).

Although gene expression in *T. gondii* appears to be transcriptionally regulated, conventional cis-acting eukaryotic promoters such as the TATA box or SP1 motif are notably absent (see, for example, Soldati and Boothroyd, 1995; Mercier *et al*., 1996; Nakaar *et al*., 1998; M. Berriman and J. Ajioka, personal observation). In searches for putative promoter elements, upstream sequence analysis of several genes has revealed short repeats with a highly conserved consensus T/AGAGACG heptanucleotide core element that qualitatively act like SP1 elements (Soldati and Boothroyd, 1995; Mercier *et al*., 1996; Nakaar *et al*., 1998). As with *Plasmodium* spp., general mechanisms controlling gene expression remain elusive and large-scale analysis of gene expression should define expression patterns that may guide further investigations.

While the *T. gondii* genome has been largely sequenced, there has been slow progress in gene finding and annotation. Despite this, researchers are using printed cDNA microarrays to address fundamental questions in the development of the parasite and its interaction with a host (Blader *et al*., 2001; Cleary *et al*., 2002). The present generation of microarrays available is made from variant and stage-specific ESTs relating to the asexual tissue cyst cycle unique to *T. gondii* and its close relatives. Several published studies have used a cDNA microarray generated from the in vivo bradyzoite EST library (Manger *et al*., 1998a). The original study characterized in vitro expression changes during high pH shock of infected tachyzoites, a treatment previously shown to result in tachyzoite-to-bradyzoite differentiation (Soete *et al*., 1994; Weiss *et al*., 1995). The majority of genes showed little expression difference between bradyzoites and tachyzoites but

revealed a new surface antigen, regulatory and metabolic enzymes, and secretory organelle proteins that showed clear expression differences (Cleary *et al*., 2002). To extend this study, mutants were selected by both chemical and insertional mutagenesis to lack in vitro differentiation (Matrajt *et al*., 2002; Singh *et al*., 2002). The microarray analysis of all mutants showed decreased expression of those genes identified in the original study and generally showed tachyzoite-like expression profiles when cultured under "bradyzoite conditions". A hierarchy of genes associated with bradyzoite formation was identified, suggesting a "cascade" model for controlling transcript levels (Singh *et al*., 2002).

2.3. *Eimeria spp*

In contrast to *T. gondii*, *Eimeria* spp. have a simple direct life cycle through a single host that is composed of sequential phases of asexual reproduction (schizogony) in the intestinal tract followed by a final sexual phase where gametogenesis, zygote formation, and meiosis result in the fecal shedding of a vast number of highly infective sporozoites (Hammond, 1982; see Figure 1). In avian *Eimeria* spp., several lines have been selected to complete the life cycle in a fewer number of asexual cycles, hence limiting the number of parasites produced and damage to the gut (Jeffers, 1975). In an effort to understand the genetic basis for the "precocious" development phenotype, a genetic map was established in *E. tenella* using a variety of DNA-based markers (Shirley and Harvey, 1996; Shirley and Harvey, 2000). In a cross between a "precocious" parent and a drug-resistant parent, 443 markers were mapped using 22 recombinant progeny, resulting in 16 linkage groups that defined 12 chromosomes. A linkage group on chromosome 2 showed significant association with precocious development and a linkage group on chromosome 1 showed significant association with resistance to the anticoccidial drug Arprinocid (Merck Research Laboratories).

In order to exploit the genetic map for positional cloning and gene identification in general, the sequencing of the nuclear genome of *E. tenella* H strain is being carried out using the whole-genome shotgun approach (Shirley *et al*., 2004). Previous and current evidence suggests that the genome is approximately 60 Mb, distributed amongst 14 chromosomes ranging in size from 1 Mb to >6 Mb (Shirley, 1994; **http://www.sanger.ac.uk/Projects/E_tenella/**). Complementary to this whole-genome sequencing effort, the complete sequence of the two smallest chromosomes of *E. tenella* H strain is being generated (Shirley *et al*., 2004). Chromosome 1 (∼1.0 Mb) and 2 (∼1.2 Mb) have been implicated via genetic linkage mapping, with resistance to the anticoccidial drug aprinocid and accelerated parasite growth, respectively. Preliminary analysis reveals that while the *E. tenella* genome is highly enriched in repetitive sequences, the distribution of these elements is markedly different between the two smallest chromosomes. Analysis of the chromosome 1 sequence reveals the presence of the repetitive heptamer TTTAGGG, which commonly characterizes the telomeres of other protozoan parasites including *P. falciparum*. A previously identified low-complexity repeat, GCA/TGC, has been found in arrays up to ∼20 triplets interspersed in both coding and noncoding sequence (Jenkins, 1988; Shirley, 1994; Shirley *et al*., 2004). This pattern of

low-complexity regions in coding sequence does not appear to follow phylogenetic lines as they do not appear to be present in *T. gondii*.

2.4. *Theileria spp*

The life cycle of *Theileria* spp. parallels that of *Plasmodium* spp., with some unusual twists. Asexual reproduction begins with sporozoite infection of the vertebrate host lymphocytes where schizogony occurs in synchrony with cell division (for review, see Norval *et al*., 1992). In certain species, the lymphocytes exhibit phenotypic traits reminiscent of transformed tumor cells. A proportion of these go on to infect erythrocytes within which they form gamonts that are ingested by the tick. The gamonts transform into micro- and macrogametocytes that fuse to form a zygote that undergoes meiosis, resulting in sporozoite formation (see Figure 1). Since the major disease caused by *Theileria* is in bovines, *T. parva*, the parasite responsible for the African cattle disease "East Coast Fever" was chosen for genome analysis (Nene *et al*., 1998).

The nuclear genomes of *Theileria* spp. and specifically *T. parva* are amongst the smallest analyzed thus far amongst apicomplexans. The genome consists of four chromosomes ranging in size from about 2.2 to 3.2 Mb for a total of approximately 10 Mb (Nene *et al*., 1998; Nene *et al*., 2000). The genome has an average G+C content of 31% and appears to have very little dispersed repetitive DNA. The paucity of repetitive DNA, apparent high gene density, with introns that tend to be few and short compared to other apicomplexans, contributes to making this a very compact genome.

2.5. *Cryptosporidia spp*

Cryptosporidium spp. infect a wide range of mammalian species with similar pathologies (for recent review, see Fayer *et al*., 1997). *C. parvum* is a major source of water and food-borne contamination, causing a self-limiting diarrhea in normal patients, but it can result in a severe life-threatening disease in the immunocompromised. There are currently no effective therapies for human infection. The life cycle of *Cryptosporidium* spp. generally resembles that of a Coccidian except that it invades only the intestinal cell membrane and does not enter the cytoplasm. Also, microgametes do not exflagellate, and sporulation resulting in four sporozoites occurs in the gut allowing both fecal shedding and autoinfection.

C. parvum is unusual in that it appears to lack both a mitochondrion and an apicoplast with a highly compact nuclear genome consisting of eight chromosomes ranging in size from 1.04 to 1.54 Mb (Blunt *et al*., 1997; Caccio *et al*., 1998; Piper *et al*., 1998). In contrast to other apicomplexan genomes, for the *C. parvum* genome, a complete HAPPY map provided a detailed physical description of the genome prior to genomic sequence assembly (Piper *et al*., 1998). This map, in conjunction with a random shotgun genomic sequence to ~13X coverage, revealed a 9.1-Mb genome distributed across eight chromosomes with a G+C content of 70% (see Table 1). Just over 3800 genes are predicted, with an average coding

sequence of about 1.8 kb, and of which only 5% are estimated to contain introns. Unlike *Plasmodium* spp. and *E. tenella*, *C. parvum* coding sequences are not enriched with low-complexity sequences. The absence of organelles and lack of obvious surface protein families accounts at least in part for the relative paucity of genes compared to the ~5300 estimated in *P. falciparum*. Although some putative mitochondrial coding sequences were identified, the absence of genes encoding proteins critical to electron transport and the Krebs cycle indicate that these parasites do not use oxidative phosphorylation but likely rely on glycolysis for ATP production. Other metabolic processes such as fatty acid and nucleotide synthesis are also comparatively limited. The lack of key enzymes in these pathways suggests that *C. parvum* relies heavily on scavenging and may also explain why some conventional drugs are ineffective. Nevertheless, the complete genome sequence has identified some traditional and new candidates for chemotherapeutic intervention.

3. Bioinformatics

Over the last decade, species-specific and nonspecific databases for Apicomplexans have been developed as repositories for sequence data, with some including associated nonsequence-based data (see Table 2). At present, the available resources vary tremendously between organisms, but the data is rapidly changing and gaining in amount as well as quality. Malaria databases are the most advanced following the completion of *P. falciparum* genome sequence almost 2 years ago, covering a wide variety of data types including genomic, proteomic, and expression data.

Parasite-associated databases have many different styles of user interface often depending on where they were constructed, but the underlying architecture may be either flat-file, relational/object-oriented, or a combination of the two. Early databases were flat-file project-specific databases, mostly from the EST sequencing projects and the initial genome sequencing efforts. Many of these flat-file databases are still in use today as they provide an easy way to share information, and their information can be easily opened using a wide variety of spreadsheet or word-processing software, for example, the *T. gondii* clustered EST database at the University of Pennsylvania (**http://paradb.cis.upenn.edu/toxo1/index.html**). This database was originally assembled using the cap2 program (Huang, 1996) and has a basic user interface with BLAST, text searching, and total database download tools incorporated. However, the limited scope of flat-file databases has led to the more recent development of complex general databases based on a combination of flat-file and relational data structures. Examples include the *Plasmodium* genome resource PlasmoDB (**http://www.plasmoDB.org**), the *Toxoplasma* genome resource ToxoDB (**http://www.toxodb.org**), and the *Cryptosporidium* genome resource CryptoDB (**http://cryptodb.org**).

PlasmoDB for example, is able to incorporate completed sequence information for *P. falciparum*, as well as data from other related projects. These include alternative species sequencing efforts, RNA (EST, SAGE, and microarray) and protein expression profiling, genetic organization, and population structure studies. Many tools have been built into the user interface for the researcher to find, relate, and understand data, including BLAST (with several user-defined options),

text searching for sequence retrieval, XCluster (for expression data), protein identification, and prediction tools as well as various motif-searching tools (for further details, see **http://www.plasmodb.org/restricted/Tools.shtml**). Since very few *P. falciparum* gene/proteins have been characterized, these tools combined with the database structure now allow a researcher to find a gene and retrieve information on its expression changes throughout a process, for example, parasite invasion of a red blood cell.

The ability to integrate data from many different sources has allowed scientists to ask questions that were previously impossible to address. This has shifted the focus to the interpretation and validation of genomic organization, predicted protein structure, and putative protein function. An example was the application of new computer-based analysis methods for cross-species gene discovery (Ajioka *et al*., 1998). Using the data generated further, bench-based analysis was carried out and published (Manger *et al*., 1998b).

Over the next few years, the sequences for several other phylum members are likely to be completed and then the task of data integration and database building begins in earnest.

Acknowledgments

We are grateful to David Ferguson, David Walliker, and Michael White for providing useful insight into apicomplexan life cycles, apicomplexan genetics, and the cell cycle respectively. Funding for this work was provided by the BBSRC (JWA)

Specialist Review

Reverse vaccinology: a critical analysis

Guido Grandi
Chiron Vaccines, Siena, Italy

1. Introduction

When attacked for the first time by a new pathogen, our organism responds through the activation of the two immune defense pathways known as innate immune response and adaptive immune response. While the innate response has the peculiarity of being nonspecific but very rapid and has the role of greatly attenuating the potentially devastating effects of pathogen invasion, the adaptive immune response is pathogen–specific. It takes a few weeks to be fully activated, and not only is it usually capable of eliminating the pathogen but it also protects our organism from subsequent aggressions. The adaptive immune response works through the recognition of few specific pathogen components that become the targets of cell- and/or antibody-mediated responses that ultimately kill the pathogen. The identification of these components and their administration before primary infection prevent the outbreak of the disease and represent the tasks of modern vaccinology. In this respect, vaccinology can be seen as a "search-for-the-needle-in-the-haystack" type of undertaking, as it requires the identification of the very few protective antigens among several hundred pathogen components.

With their pioneering work published in Science in 2000, Pizza *et al*. (2000) proposed a revolutionary approach to vaccine discovery. The approach, named "reverse vaccinology" (Rappuoli, 2000), stems from the simple and straightforward consideration that, if in a given pathogen protein antigens with protective immunological properties exist, their coding genes must be sitting somewhere in the pathogen genome. Therefore, by providing the complete list of proteins, the knowledge of genome sequence offers the opportunity to systematically analyze each protein until the ones having the desired properties are unveiled. In its most classical application, reverse vaccinology can be outlined as follows: (1) genome sequencing of the pathogen of interest, (2) gene selection by in silico analysis of the genome, (3) high-throughput cloning and expression of selected genes, (4) purification of recombinant proteins, and (5) identification of potential vaccine candidates by systematic analysis of all purified proteins using appropriate in vitro and/or in vivo assays. Subsequently, it became clear that gene selection could be optimized by applying, in addition to the in silico analysis, other criteria that make the entire process more efficient (Grandi, 2004). These criteria include DNA microarray and proteomics analyses.

The present work will first review published as well as unpublished examples of reverse vaccinology and then, on the basis of the results presented, it will attempt a critical analysis of the technology with the aim of facilitating future vaccine discovery projects.

2. Examples of reverse vaccines

2.1. Group B *Neisseria meningitidis*

Meningococcal meningitis and sepsis are caused by *Neisseria meningitidis*, a gram-negative, capsulated bacterium, classified into five major pathogenic serogroups (A, B, C, Y, and W135) on the basis of the chemical composition of their capsular polysaccharides (Gotschlich *et al*., 1969a,b). Very effective vaccines based on the capsular polysaccharides against Meningococcus C are already on the market, and anti-Meningococcus A/C/Y/W polyvalent vaccines are expected to be launched in the near future. However, because of the poor immunogenicity of its capsular polysaccharide, no vaccines are available yet against MenB, the meningococcal serotype responsible for a large proportion (from 32 to 80%) of all meningococcal infections in industrialized countries (Scholten *et al*., 1993). Because of the usefulness of the capsular polysaccharide, a few vaccines based on surface-exposed proteins have been tested, although some membrane-associated proteins have been shown to elicit protective bactericidal antibodies (Poolman, 1995; Martin *et al*., 1997). However, many of the major surface protein antigens in MenB show sequence and antigenic variability, thus failing to confer protection against many heterologous strains. Therefore, the challenge for anti-MenB vaccine research is the identification of highly conserved antigens eliciting protective immune responses (bactericidal antibodies) against a broad range of MenB isolates. To achieve this goal, a new approach called reverse vaccinology was developed and applied for the first time in Chiron Vaccines (Pizza *et al*., 2000).

The MenB genome sequence (Tettelin *et al*., 2000) was submitted to computer analysis to identify genes potentially encoding surface-exposed or exported proteins. Of the 650 proteins thus predicted, approximately 50% were successfully expressed in *Escherichia coli*. The recombinant proteins were purified and used to immunize mice and the immune sera were tested for bactericidal activity, an assay that strongly correlates with protection in humans (Goldscheider *et al*., 1969). Twenty-eight sera turned out to be bactericidal. To analyze sequence conservation of the protective antigens, the nucleotide sequences of the corresponding genes from a large panel of *N. meningitidis* clinical isolates (>250) were compared. This analysis led to the identification of five highly conserved antigens whose combination induced antibodies capable of killing most of the meningococcal strains so far tested in the complement-mediated bactericidal assay. Phase I clinical studies are about to be completed and will soon establish the ability of these antigens to induce bactericidal antibodies in humans.

2.2. *Streptococcus pneumoniae*

Streptococcus pneumoniae is the most common cause of fatal community-acquired pneumonia in the elderly, and is also one of the most common causes of middle ear infections and meningitis in children. Penicillin resistance is global in *S. pneumoniae* and the incidence of resistance to several other antibiotics is becoming a serious medical concern. Although a heptavalent glycoconjugate vaccine is on the market and is highly effective against 80% of the *S. pneumoniae* isolates in the United States (Obaro, 2002), the vaccine only covers 60% and 40% of the strains in Europe and in the rest of the world, respectively. Furthermore, considering the adaptive capacity of *Pneumococcus*, the selective pressure exerted by population-wide vaccination may result in the emergence of strains that are not included in the current pneumococcal vaccine.

Taking advantage of the availability of the genome sequence of a clinical isolate of *S. pneumoniae* (Tettelin *et al*., 2001), researchers at MedImmune selected 130 genes with sequence motifs common to secreted proteins and virulence factors. Of the 130 proteins, 108 were expressed, purified, and used to immunize mice. Six of the proteins were shown to confer protection against a disseminated mouse model of *S. pneumoniae* infection (Adamou *et al*., 2001). Although no data were reported on the conservation of these protective antigens among the plethora of *S. pneumoniae* subtypes, these results clearly show, as is the case for MenB, that protein antigens can become important components of new generation anti-*S. pneumoniae* vaccines.

2.3. *Porphyromonas gingivalis*

Porphyromonas gingivalis is a gram-negative bacterium that grows and colonizes the human oral cavity and has been implicated in the etiology of chronic adult peridontitis (The American Academy of Periodontology, 1999). By following an approach very similar to the one described for *N. meningitidis*, 120 genes were selected on the basis of the predicted localization of their coded proteins on the surface of the bacterial membrane. The selected genes were expressed in *E. coli* and tested for their capacity to be recognized by a panel of antisera against *P. gingivalis*. The subset of proteins positive to the immunological analysis was subsequently used for immunization of mice, and these were challenged with live bacteria in a subcutaneous abscess model. Two of these proteins, both homologous to the *Pseudomonas* sp. OprP proteins, demonstrated significant protection in the animal model and, therefore, were proposed as promising candidates for an anti-peridontitis vaccine (Ross *et al*., 2001).

2.4. *Group B streptococcus*

Group B streptococcus (GBS) is the major cause of neonatal sepsis in the industrialized world, accounting for 0.5–3.0 deaths/1000 live births. Eighty percent

of the GBS infections in newborns occur within the first 24–48 h after delivery (Schuchat, 1998). This group is known as early onset disease, and is generally caused by direct transmission of the bacteria from the mother to the baby during labor. A second peak of infections, which begins a week after birth and continues through the first month of life, is known as late onset disease and is usually nosocomial. The elderly are also susceptible to GBS infections, and, in the last few years, the incidence of such infections is growing to a level of particular concern.

Protection in humans against invasive GBS disease correlates with high titers of anticapsule antibodies. Since these antibodies can pass through the placenta, children born from mothers with high titers of anti-GBS antibodies have a negligible risk of being infected by GBS in the first months of life.

Experiments in mice have demonstrated that glycoconjugates of capsular polysaccharide with tetanus toxoid carrier protein can induce an immune response in pregnant females, which can confer protection in the pups against lethal GBS challenge (Paoletti *et al*., 1994). These data suggest that immunizing women before they become pregnant could effectively prevent the majority of invasive GBS disease in newborns. Unfortunately, there are at least nine capsular serotypes, and antibodies against any one of these fail to confer protection against the other serotypes (Berg *et al*., 2000; Davies *et al*., 2001; Hickman *et al*., 1999; Lin *et al*., 1998; Suara *et al*., 1998). An alternative approach would be to identify a few conserved protein antigens eliciting protective immunity against most, preferably all, GBS serotypes. In line with the reverse vaccinology strategy, researchers at Chiron Vaccines used a series of computer programs to identify, among all genes of the GBS genome (Tettelin *et al*., 2002), those encoding proteins carrying signal peptides (PSORT, SignalP), transmembrane spanning regions (TMPRED), lipoproteins and cell-wall anchored proteins (Motifs), and proteins with homology to known surface proteins in other bacteria (FastA). This analysis ultimately led to the selection of 473 genes that were subjected to the high-throughput expression purification procedure. Overall, 357 recombinant proteins were successfully purified and tested in the maternal active immunization assay. According to this assay (Paoletti *et al*., 1994), female mice are first immunized with the recombinant antigens, then mated, and the resulting offspring are challenged with a lethal dose of GBS within the first 48 hours of life. For the pups to be protected, immunization has to induce in the mothers sufficiently high levels of antibodies, which can cross the placenta and reach the mice in utero. Using this model, four new antigens were found to confer a statistically significant protection (survival rate >30% over the background, with a $P_{\mathrm{val}} < 0.05$) against at least one of the GBS strains used for challenge. Interestingly, antigen combinations were capable of protecting up to 100% of the animals from lethal doses of different GBS strains, indicating the additive, if not synergistic, effect of antigen coadministration. A particular combination of these antigens is currently in the development phase.

2.5. *Group A streptococcus*

Group A streptococcus (GAS) can colonize human throat and skin, causing, in general, relatively mild diseases but, nevertheless, very costly in terms of health

care visits, workdays lost by parents, and number of schooldays lost (Cunningham, 2000). Like GBS, GAS can also cause severe invasive diseases including scarlet fever, a frequently lethal toxic shock syndrome, and necrotizing fasciitis. In this latter respect, GAS is also known as the flesh-eating bacterium since it can turn a small wound into massive necrosis, which necessitates emergency measures including extensive surgical intervention and tissue reconstruction. Perhaps of more importance are rheumatic fever (RF), rheumatic heart disease (RHD), and glomerulonephritis, the autoimmune sequelae that can follow, in some countries at high frequencies, throat and skin infection, and scarlet fever. Overall, it has been estimated that more than 600 million people are annually infected by GAS worldwide, 500 thousand of whom die because of GAS invasive disease and RHD.

There is no vaccine available for GAS, and attempts to identify protective antigens have so far been unsuccessful (Dale, 1999). A major immunodominant antigen, the M-protein, has shown type-specific protection in both humans and animal models. However, there are over 124 known serotypes of this protein; therefore, although M-protein-based vaccines are being attempted (Hu *et al*., 2002), their efficacy still awaits confirmation in the clinics, and they are unlikely to provide broad coverage against GAS infections.

Starting from the available GAS genome sequences (Ferretti *et al*., 2001), researchers at Chiron used in silico analysis and DNA microarray technology to identify highly expressed, membrane-associated proteins. In total, 285 genes were selected and successfully expressed in *E. coli* as either His-tagged proteins or GST fusions. An adult mouse model of invasive infection based on the intraperitoneal challenge of CD1 mice with a virulent M1 serotype strain (LD_{50} = 10 CFUs) was then used for vaccine candidate selection. Protection in this model implied the elicitation of circulating opsonic/bactericidal antibodies capable of preventing systemic infection in the animals. Six antigens have so far been identified showing a statistically significant protective activity. Particularly promising is one antigen, GAS40, which conferred a survival rate above 50% and elicited opsonic antibodies. The antigen is also highly conserved (homology $>$98.5%) among a large panel of GAS clinical isolates belonging to different M-serotypes.

2.6. *Chlamydia trachomatis*

Like all obligate intracellular pathogens, for its survival and propagation, the gram-negative bacterium *Chlamydia trachomatis* must accomplish several essential tasks, which include adhering to and entering host cells, creating an intracellular niche for replication, exiting host cells for subsequent invasion of neighboring cells, and also avoiding host defense mechanisms (Stephens, 1999). To carry out all these functions, *C. trachomatis* has developed a unique biphasic life cycle involving two developmental forms, a sporelike infectious form (elementary bodies, EB), and an intracellular replicative form (reticulate bodies, RB). Adhesion, host cell colonization capabilities, and ability to cope with the host defense mechanisms when outside the cell presumably rely in large part on EB surface organization.

Its unique life cycle renders *C. trachomatis* very successful in avoiding host immune responses and establishing a chronic infection, often leading to serious

diseases (Stephens, 1999). Chronic infection of the ocular mucosa can result in blindness, whereas, in the female, infection of the upper genital tract can lead to pelvic inflammatory disease, ectopic pregnancy, and sterility. Indeed, *C. trachomatis* infection is one of the most serious causes of both male and female sterility in industrialized countries. Sexually transmitted disease (STD) induced by *C. trachomatis* have also been implicated as a risk factor for the sexual transmission of other serious pathogens such as the human immunodeficiency virus (HIV) (Ho *et al*., 1995).

In spite of years of efforts by several research groups around the world, a vaccine against human chlamydial infection is still unavailable. This may be attributed to several reasons, among which are the difficulty in culturing large quantities of the pathogen (limiting the purification of antigens to be tested in vaccine studies) and the inability to carry out any kind of genetic analysis. As a consequence of these limitations, vaccine studies have been restricted to very few chlamydial antigens, mostly tested in the mouse, intravaginally challenged with either human or mouse-adapted chlamydial isolates. From these studies, as well as from epidemiological data and vaccine trials in humans, it has been established that protection against chlamydial infection most likely correlates with both the elicitation of a CD4+ T cell-specific cytotoxic activity and a neutralizing antibody response. The data also indicate that none of the antigens so far tested is capable of conferring a consistent, robust protection in the mouse, the only efficacious vaccination being represented by the intravaginal administration of live *Chlamydia*, which protects the mouse against subsequent *C. trachomatis* challenges (Ramsey *et al*., 1999).

With this background, researchers at Chiron scanned the *C. trachomatis* genome in search of genes encoding putative surface-exposed antigens. Ninety-three genes were selected, cloned in *E. coli,* and the corresponding recombinant proteins purified. Each purified protein was injected into mice and the immune sera were used in two types of assays: FACS analysis of EBs to confirm their surface exposure (Montigiani *et al*., 2002) and in vitro neutralization of infection (Finco *et al*., 2005). Forty-eight proteins out of 93 were positive to the FACS assay, and 13 proteins elicited antibodies with neutralizing activity in vitro. These antigens, never described before as being capable of eliciting neutralizing antibodies, represent potential vaccine candidates and are currently under analysis for their protective activity in vivo in the mouse model of infection.

3. A critical analysis of reverse vaccinology

The available examples of reverse vaccinology offer the opportunity to critically analyze the technology and to discuss a few take-home lessons that might help to improve and optimize its future applications.

The first important lesson is that the selection of the correlate-of-protection assay used for the high-throughput screening of the antigens plays a crucial role for the final success of the technology. It is intuitive that, in the absence of a robust assay that correlates with protection in humans, the labor-intensive process, which goes from genome sequence to gene selection and high-throughput expression and screening of antigens, results in a useless effort. In general, more than one animal

model of infection has been described for the same pathogen. However, not all of them are supported by convincing data that demonstrate their correlation with the human system. Typical examples are the mouse models used for GAS. In GAS, the protective capacity of vaccine candidates are investigated using either mucosal immunization followed by intranasal infection (Schulze *et al*., 2003; Hall *et al*., 2004), or systemic immunization followed by intraperitoneal challenge (McMillan *et al*., 2004; Kawabata *et al*., 2001). According to the first model, protection is largely mediated by the elicitation of mucosal IgA, whereas in the second model, mice survival only occurs if the injected antigen is capable of inducing bactericidal/opsonic-circulating antibodies. While it is still not clear whether in humans the presence of bactericidal antibodies is strictly necessary to prevent streptococcal infection, it is obvious that the selection of one model or the other has important consequences on the probability that the antigens found to be protective in the mouse can work in humans as well.

The second important take-home message is that the "Holy Grail" in vaccinology, namely, the antigen that alone elicits neutralizing immune responses against all the clinical isolates of a given pathogenic species, can exist (examples are the tetanus and diptheria toxins) but is very rare. Even with reverse vaccinology that has the power to scan the protective activity of most of the proteins belonging to a given pathogen, the number of such universal antigens that are being identified is limited. More realistically, protective antigens are found that altogether have the potential to provide broad cross-protection by virtue of the fact that each of them is conserved among specific pathogen subtypes. This implies that for a successful application of reverse vaccinology, the availability of the genome sequence of only one isolate may be largely insufficient. This statement is supported by the discovery that genomic sequences from different isolates of the same pathogen have shown numerous genetic differences. This is true for *Mycobacterium tuberculosis* (two genomes), *Helicobacter pylori* (two genomes), *Chlamydia pneumoniae* (four genomes), *Staphylococcus aureus* (five genomes), *Streptococcus pyogenes* (five genomes), *Yersinia pestis* (three genomes), *Escherichia coli* (four genomes), and *Group B Streptococcus* (seven genomes, unpublished).

Undertaking a reverse vaccinology project with the availability of a single genome sequence has two important implications. First, once a vaccine candidate has been identified, its similarity among as many worldwide clinical isolates as possible needs to be investigated. A similar approach has been followed in the reverse vaccinology of *N. meningitidis,* whereby the sequence similarity of the five vaccine candidates was determined in over 250 isolates before moving to the development phase. Second, protective antigens only expressed in isolates not belonging to the subtype of the sequenced strain will be missed. This limits, quite substantially, the probability of finding a sufficiently large group of antigens whose combinations could ultimately lead to an effective vaccine formulation.

The third important lesson learnt is that the conservation of a protective antigen among a group of isolates does not necessarily translate into the capacity of such a conserved antigen to confer protection against all the isolates in which the antigen is conserved. Quite a few MenB, GBS, and GAS selected antigens that were expected to be cross-protective on the basis of their gene sequence conservation, in fact, failed to protect mice against heterologous challenge. This apparent paradox

was experimentally solved by demonstrating that even if conserved, the relative abundance of an antigen on the bacterial surface can vary quite substantially from strain to strain. This fluctuation may be due to different levels of expression, different stability, and different expression of other bacterial components that ultimately mask the protective antigen (this is particularly true in the case of capsulated bacteria where, depending upon environmental conditions, variation in capsule expression is well-known to occur among strains, and even within the same strain). Now, since the level of expression is approximately proportional to the probability that the antigen will be recognized by the effector functions of the immune system, pathogens having a poorly expressed antigen are less exposed to antigen-specific immune responses. This observation implies that the extent of cross-protection conferred by a protective antigen cannot be extrapolated only by its degree of gene conservation but rather must be experimentally verified. In practical terms, if the assay for antigen selection is based on animal immunization followed by animal challenge with the pathogen, multistrain challenge is necessary to demonstrate the cross-protection efficacy of the candidate.

One last comment deserves some attention and future homework. One question that is still open in vaccinology is whether or not all protective antigens fall into the category of those antigens that are naturally highly immunogenic. If we look at the list of subunit-based vaccines that are currently on the market, the answer seems to be, definitely yes. Tetanus toxin, diphtheria toxin, *Bordetella pertussis* vaccine components, and capsular polysaccharides, to give some examples, are all highly immunogenic and elicit strong antibody responses in humans during infection. Obviously, a conclusive answer to this question has important implications on the future strategies of vaccine discovery. Reverse vaccinology does not take into account the immunogenic properties of antigens, and the selection of proteins eligible for the high-throughput screening phase is based on their location in the cell (surface and membrane-associated antigens) and their known or predicted function (virulence factors, toxins, etc.). These selection criteria impose a substantial amount of work in the subsequent gene cloning, protein expression and purification, and candidate-identification steps, and may miss some good candidates. Should only the naturally immunogenic antigens be the relevant ones for vaccine applications, strategies based on (1) immunogenic antigen selection and (2) antigen expression purification and screening are expected to be more efficient. One such strategy has been recently described (Etz *et al*., 2002). *Staphylococcus aureus* genomic DNA was fragmented and the derived fragments were cloned in the *E. coli* LamB and FhuA expression systems. In so doing, *E. coli* libraries with *S. aureus* protein domains expressed on the surface of the cells were generated. These libraries were screened with human sera with high anti-*S. aureus* antibody titers and opsonic activity, and positive clones that specifically reacted with the sera were identified. Finally, the *S. aureus* antigens expressed on the surface of the positive clones were tested for their capacity to confer protection in a mouse model of infection, and four antigens were reported to be protective. These data indicate that approaches based on the preselection of immunogenic antigens can be very effective in vaccine candidate identification. However, if protective antigens exist that are not naturally immunogenic, these antigens are necessarily lost.

To establish, once and for all, whether all protective antigens are immunogenic, it would be sufficient to take the same pathogen, search for protective antigens using both reverse vaccinology and the immunogenic protein selection approach, and see whether or not the two strategies identify the same vaccine candidates.

Short Specialist Review

The staphylococci

Steven R. Gill
The Institute for Genomic Research, Rockville, MD, USA

1. Introduction

The staphylococci are a major cause of nosocomial and community-acquired infections, ranging in severity from minor skin inflammation to life-threatening systemic infections that are increasingly resistant to antibiotics. The two major staphylococcal pathogens, *Staphylococcus aureus* and *Staphylococcus epidermidis*, are found on 30–70% (Peacock *et al*., 2001) and 100% (von Eiff *et al*., 2002) of the human population, respectively, where they live as commensals on the skin and mucous membranes. Infections develop when the staphylococci contaminate a breach in the host cutaneous system that occurs as a result of trauma or cuts. Nosocomial *S. aureus* infections are caused by a small number of successful epidemic clones (Lindsay and Holden, 2004; Johnson *et al*., 2001) and occur in hospitalized patients who are often subjected to treatments with needles or catheters and who have comprised immune systems. Community-associated *S. aureus* (CASA), previously associated with common skin infections (Stevens, 2003), have increasingly been linked to severe infections and lethal hemolytic pneumonia in children (Lindsay and Holden, 2004; Gillet *et al*., 2002), likely as a result of the acquisition of the Panton–Valentine leukocidin gene (*PV-luk*) (Dufour *et al*., 2002; Herold *et al*., 1998). In contrast, infections caused by the less-aggressive pathogen, *S. epidermidis*, primarily remain associated with implanted medical devices (von Eiff *et al*., 2002).

Acquisition of resistance to most classes of antimicrobial agents has made control of staphylococcal infections increasingly difficult. Widespread treatment of staphylococcal infections in the 1960s led to the emergence of methicillin-resistant *S. aureus* (MRSA) and *S. epidermidis* (MRSE), which continue to persist in both the health care and community environments (Stevens, 2003). In the United States and Japan, ~60% of nosocomial *S. aureus* isolates are resistant to methicillin and some strains have developed resistance to more than 20 different antimicrobial agents (Paulsen *et al*., 1997). The glycopeptide antibiotic, vancomycin, has been viewed as the last-resort therapy against most strains of multidrug-resistant staphylococci (Walsh, 1999). However, its effectiveness has been limited by the emergence in 1997 (CDC, 1997) of *S. aureus* with intermediate levels of resistance to vancomycin (VISA or vancomycin intermediate *S. aureus*) and the most recent emergence of *S. aureus* with high levels of resistance to vancomycin (VRSA or vancomycin resistant *S. aureus*) (CDC, 2002).

The virulence of these two pathogens is multifactorial and mediated by a wide array of extracellular toxins and surface structures. Of the two organisms, *S. aureus* produces the largest number of potential virulence factors, including hemolysins, enterotoxins, exfoliative toxins, proteases, leukocidins, and toxic shock syndrome toxin (Projan and Novick, 1997), which contribute to *S. aureus*'s aggressiveness and success as one of the most successful opportunistic human pathogens. In contrast, *S. epidermidis* produces far fewer potential virulence factors, the exception being an expanded family of phenol soluble modulins (Gill *et al*., 2005). In both species, virulence is thought to be regulated by global gene regulators, such as *agr* and *sar* (Novick, 2003), which respond to environmental signals, thereby allowing the bacteria to differentially express selected virulence factors in response to environmental or host signals.

2. Staphylococcal genomes

Seven *S. aureus* genomes (Gill *et al*., 2005; Holden *et al*., 2004; Baba *et al*., 2002; Kuroda *et al*., 2001; or available on-line at **http://www.genome.ou.edu/staph**) and two *S. epidermidis* genomes (Gill *et al*., 2005; Zhang *et al*., 2003) have been sequenced and are publicly available (Table 1). Whole-genome analysis of these genomes demonstrates that they are syntenic throughout a well-conserved core region, with differences being the result of genomic elements including genome islands (νSa, νSe, SSCmec, and SSC-like elements), integrated prophage, IS elements, composite transposons, and integrated plasmids, which are associated with disease and virulence (Table 1). Depending upon the isolate, these genomic elements make up approximately 10–20% of the *S. aureus* genomes and ∼10% of the *S. epidermidis* genomes; a proportion that is similar to that found in other gram-positive pathogens, such as group A Streptococcus (∼10%) (Beres *et al*., 2002) and *Enterococcus faecalis* (25%) (Paulsen *et al*., 2003). The core genome is composed of genes associated with central metabolism, housekeeping functions and surface proteins required for growth and survival in the host. Genes outside of the core genome are frequently species-specific genes or virulence factors carried on one of the six pathogenicity genomic islands (νSa) identified in the sequenced *S. aureus* genomes or two (νSe) in the sequenced *S. epidermidis* genomes. The νSa islands carry approximately one-half of *S. aureus* virulence factors, and the presence or absence of individual νSa determines the pathogenic potential of isolates within this species. For example, *S. aureus* MRSA252 (Holden *et al*., 2004) and MW2 (Baba *et al*., 2002) contain novel islands, SaPI4 and νSa3 respectively, that likely contribute to the virulence of these isolates. A genome island in *S. epidermidis*, νSeγ, encodes multiple members of the phenol soluble modulin (psm) family, which is likely a key virulence factor in this species (Gill *et al*., 2005). Overall, the paucity of pathogenicity genomic islands in *S. epidermidis* when compared to *S. aureus* is a direct reflection of the greater pathogenic potential of *S. aureus*. The two sequenced *S. epidermidis* differ in their ability to form a biofilm, the key factor in their role as pathogens. A comparison of RP62a (a biofilm producer) and ATCC12228 (a biofilm nonproducer) revealed that the key differences are the presence of the cell wall–associated biofilm protein (Bap) or

[b]HA-MRSA: Hospital-acquired MRSA (methicillin-resistant *S. aureus*).

[c]CA-MRSA: Community-acquired MRSA.

[d]CA-MSSA: Community-acquired MSSA (methicillin-sensitive *S. aureus*).

[e]HA-MRSE: Hospital-acquired MSRE (methicillin-resistant *S. epidermidis*).

Bap homologous protein (Bhp) and of the intercellular adhesin locus (*icaA,B,C,D*) that encodes the polysaccharide intercellular adhesin that participates in biofilm formation (Gill *et al*., 2005). Acquisition of virulence factors and formation of genome islands in staphylococci likely occur as a result of gene movement of plasmids and phage among other family members of the low-GC gram-positive bacteria. One example of this occurrence is the presence in *S. epidermidis* of a *capA,B,C* operon, which was first identified in *Bacillus anthracis* where it encodes the polyglutamate capsule, a major virulence factor. Similarly, a *Bacillus subtilis* ϕSPβ-like bacteriophage found in *S. epidermidis* RP62a has been modified to encode a nuclease and a species and RP62a specific LPXTG cell surface binding protein. Finally, VRSA occurred as a result of conjugative transfer of *Tn1546vanA* from *Enterococcus faecalis* to *S. aureus* (Weigel *et al*., 2003).

3. Concluding remarks

The emergence of CASA (Stevens, 2003) and VRSA (Weigel *et al*., 2003) demonstrates the dynamic nature of the staphylococcal genome and the role gene transfer and acquisition of virulence factors has played in the evolution of this genus. The identification of a novel pathogenicity island carrying staphylococcal enterotoxin C (*sec*) in a *S. epidermidis* isolate (S. Gill, unpublished data) illustrates the progression of this species toward a bona fide pathogen. Genome-wide comparisons of additional staphylococcal genomes, such as *Staphylococcus haemolyticus* and *Staphylococcus carnosus* that are being sequenced, will likely lead to insights into evolution of the staphylococci and novel therapeutic approaches for control of nosocomial and community-acquired infections.

1. Introduction

Infections caused by the human pathogen group A *Streptococcus* (GAS) likely were described by Hippocrates in the fifth century B.C. Historically, GAS has caused outbreaks of pharyngitis (strep throat), scarlet fever, rheumatic fever, and puerperal sepsis or "childbed fever". Although GAS commonly causes pharyngitis and skin infections, the organism recently has received considerable attention because of its ability to cause necrotizing fasciitis, a devastating infection sometimes referred to as the "flesh-eating" syndrome (Cunningham, 2000). Since the late 1980s, there has been an unexplained resurgence in several forms of severe invasive disease including necrotizing fasciitis, streptococcal toxic shock syndrome, and septicemia. It is now known that GAS causes ~10 000–15 000 cases annually of invasive infections in the United States, with a mortality rate exceeding 50% in some reports.

For more than 50 years, GAS have been classified on the basis of serological diversity in M protein, a major surface antigen and virulence factor (Cunningham, 2000). However, sequencing of the hypervariable part of the *emm* gene encoding M protein largely has replaced serological typing of strains. More than 125 *emm* types are recognized and this allelic diversity has been useful for categorizing strains for epidemiological studies. Although no one *emm* type is solely responsible for any single GAS infection type, strains expressing certain M types have been associated repeatedly with specific diseases. For example, serotype M1 and M3 strains are the leading causes of invasive infections in many western countries, and M18 strains have been commonly associated with rheumatic fever (Cunningham, 2000). Because strains of relatively few M types cause a disproportionate amount of infections, strains of these M types have been the subject of many studies. However, a classification scheme of GAS based on diversity in a single surface antigen does

not accurately reflect the extensive chromosomal and allelic diversity that exists within the species (Reid *et al*., 2001). Recombination events, many involving bacteriophages and genes encoding a wide assortment of virulence factors play an important role in generating diversity (Banks *et al*., 2002). Knowledge of the population structure of GAS and the level of naturally occurring genetic variation may help explain epidemiological observations such as rapid shifts in the predominant M serotypes causing GAS disease. Geographic and temporal differences in serotype distribution, disease frequency, and disease character are likely related to changes in GAS gene content, clonal selection, and fitness of particular strains.

2. A wealth of genome sequences

The increase in GAS disease frequency and severity has sparked renewed interest in understanding the molecular mechanisms of pathogenesis, bacterial population genetics, and vaccine development. Although host factors are undoubtedly a key factor determining infection and its outcome, a basic understanding of GAS molecular pathogenesis is needed to understand how this bacterium causes a wide range of disease types. To facilitate research and discovery, the genomes of seven GAS strains (serotypes M1, M3, M5, M6, M18, and M28) commonly causing pharyngitis and invasive disease have been sequenced recently, and additional strains are under study (Ferretti *et al*., 2001; Smoot *et al*., 2002; Beres *et al*., 2002; Nakagawa *et al*., 2003; Banks *et al*., 2004; Green *et al*., 2005; **http://www.sanger.ac.uk/Projects/S_pyogenes/**). The availability of genome sequences of M protein serotypes causing distinct diseases has yielded a tremendous amount of new information important in pathogenesis and other research.

The genome sequences have provided new insight into the extent of strain variation within and between serotypes. All strains studied thus far have a genome size of ∼1.8–1.9 Mb, similar G+C content (38.5%), six highly conserved rRNA operons, and a core group of proven and putative virulence genes. Importantly, all strains are polylysogenic, that is, contain multiple prophages or prophage-like elements that encode one or more virulence factors such as toxins. Approximately 90% of gene content is shared among strains and constitutes the core GAS genome. All strains differ in insertion sequences, small indels, and single-nucleotide polymorphisms, but the majority of variation in gene content between strains is caused by prophages or prophage-like elements. Twenty-three distinct prophages or prophage-like elements have been described thus far. As noted, an extremely important feature of these elements is that the great majority encode one or two proven or putative extracellular virulence factors such as pyrogenic toxin superantigens (PTSAgs), DNAses, a novel phospholipase A_2 (SlaA), macrolide efflux pump resistance genes, and a novel cell-wall anchored protein hypothesized to be an adhesin. Many prophage-associated virulence factor genes were unknown prior to their discovery by GAS genome sequencing projects. Other new discoveries include two-component regulators, variation in chromosomal arrangement, secreted and cell-wall anchored proteins, lipoproteins, and single-nucleotide polymorphisms between strains.

3. Prophages and variation in gene content among GAS strains

Although the existence of GAS phages was first demonstrated in the 1920s, only recently has the extent of polylysogeny and implications for several areas of GAS biology been appreciated. GAS strains vary in their prophage content, and a second level of diversity is contributed by modular recombination involving parts of prophages.

Alignment of the prophage sequences present in six available GAS genomes has revealed extensive mosaicism, presumably caused by modular recombination. Phylogenetic comparisons of individual phage genes and entire phage genomes indicate a lack of congruency, suggesting that recombination has been an important contributor to generating diversity among GAS prophages. In addition, sequencing of prophage genes such as those encoding PTSAgs (SpeA, SpeC) and SlaA from GAS strains representing distinct genetic backgrounds has identified many allelic variants, some of which may have a biologically relevant effect in pathogenesis. For example, one of the variants of SpeA (SpeA3) has been reported to have significantly more superantigen activity than the SpeA1 variant (Reid *et al*., 2001).

The genome sequences have made possible genome-wide comparisons of GAS strains. Genome comparisons by DNA–DNA microarray analysis and whole-genome PCR scanning have been used to detect differences in total gene content among strains of the same serotype (Smoot *et al*., 2002; Banks *et al*., 2004; Beres *et al*., 2004). For example, using clinical isolates from defined disease types, these methods have clearly shown that not all GAS isolates of the same M protein serotype are genetically equivalent, nor even recent clonal derivatives. Although many strains of the same serotype have a closely similar shared ("core") chromosomal gene content, strains can be highly variable in their prophage content. Inasmuch as natural competence has not been reported in GAS, it is probable that phage transduction is a primary generator of genetic diversity in this pathogen.

Two examples highlight the extent to which prophages serve as the main source of variation in gene content among strains of the same serotype (M18 and M3) (Smoot *et al*., 2002; Beres *et al*., 2002, 2004). DNA microarray analysis was performed on 36 serotype M18 strains collected over 50 years (1948–2000) from various geographic locations (Smoot *et al*., 2002). The analysis showed that prophages were the primary source of variation in gene content. Conversely, with the exception of prophages and prophage-like elements, very little variation in gene content was detected among these strains. Similarly, identity in prophage-related gene content was evident among strains collected during certain time periods and among strains involved in specific GAS outbreaks that occurred in specific geographic locations. Analogous observations were made in a recent population-based study of 255 serotype M3 strains causing two epidemics of invasive disease episodes between 1992 and 2002 in Ontario, Canada (Beres *et al*., 2004). All differences in gene content between strains were due to variation in prophage content.

4. Use of genome-wide studies to understand molecular events underlying GAS epidemics

Molecular factors that contribute to the emergence of new virulent bacterial subclones and epidemics are poorly understood. We recently studied this topic by analysis of a population-based strain sample of serotype M3 GAS recovered from patients with invasive disease (Beres *et al*., 2004). Serotype M3 strains are a leading cause of invasive GAS infections as shown by population-based surveillance studies in the United States and Canada. Patients infected with serotype M3 strains are more likely to have severe infections and die. To gain insight into molecular factors contributing to GAS subclone emergence and bacterial epidemics, a genome-wide investigative approach was used to study 255 contemporary clinical M3 strains obtained from an 11-year population-based surveillance study of invasive disease in Ontario, Canada. Genetic diversity in these serotype M3 strains was investigated by several methods including pulsed-field gel electrophoresis, DNA microarray, whole-genome PCR scanning, and PCR-based prophage genotyping to determine prophage content, *emm* gene sequencing, and single-nucleotide polymorphism (SNP) analysis (Beres *et al*., 2004). The results revealed the presence of nine distinct prophage genotypes that matched with the pulse-field gel electrophoresis patterns. However, the majority of the strains had the same prophage content as the sequenced M3-MGAS315 genome and these strains were abundant in two peaks of infection. Both DNA microarray and whole-genome PCR scanning analysis of selected strains identified virtually no differences in gene content unrelated to prophage, that is, the core genome. Sequence analysis of the *emm* gene and SNP analysis were used to further classify genetic relationships among the M3 strains. The data were used to determine that the strains were pauciclonal, with a limited number of subclone groups identified. Interestingly, statistically significant associations were present between certain prophage genotypes and GAS disease types. By applying molecular genetic techniques to epidemiological observations, temporal changes in M3 subclone gene content were discovered. Acquisition or loss of prophages, allelic variation in chromosomal genes, expansion of subclone populations, and introduction of new subclone variants were shown to contribute to peaks of infection and different infection types (Beres *et al*., 2004).

5. Insight into the emergence of drug-resistant strains: an outbreak of pharyngitis caused by macrolide resistant strains

GAS infections commonly are treated with penicillin or a related β-lactam antibiotic. Although treatment failures occur, fortunately all strains remain exquisitely susceptible in vitro to this class of antibiotics. Erythromycin and related macrolide antibiotics sometimes are used as an alternative treatment for GAS pharyngitis. In contrast to β-lactams, resistance of GAS to macrolide antibiotics was described in the late 1950s, and has increased dramatically worldwide in the last 10 years.

Recently, an outbreak of pharyngitis caused by erythromycin-resistant serotype M6 GAS strains was reported among schoolchildren in Pittsburgh, Pennsylvania (Martin *et al*., 2002). This outbreak was of particular concern because within a few months the frequency of macrolide resistant GAS increased rapidly and drug-resistant strains spread to surrounding communities. Molecular studies revealed that serotype M6 strains of a single clone were responsible and resistance was due to the presence of the *mefA* gene encoding a macrolide efflux pump.

Inasmuch as serotype M6 strains are one of the more common causes of pharyngitis and invasive infections, and no information was available about the molecular mechanism of acquisition of the *mefA* gene in the Pittsburgh case clone, we chose to sequence the genome of a genetically representative strain. Several important findings were revealed (Banks *et al*., 2003, 2004). Most importantly, we discovered that the *mefA* gene was encoded by a 58.8-kb foreign genetic element with characteristics of both a transposon and a prophage. This chimeric element was inducible under in vitro conditions and was present in all serotype M6 pharyngeal isolates tested from the Pittsburgh outbreak, as well as across multiple other serotypes from various geographic locations. These observations indicate that acquisition of the *mefA* element by horizontal gene transfer, followed by clonal expansion, were key contributors to the outbreak.

6. Expression microarray analyses

The molecular basis underlying bacterial responses to host signals during natural infections is poorly understood. To begin to address this deficit, several expression microarray studies have been done with GAS, and extensive new information has been obtained (Smoot *et al*., 2001; Graham *et al*., 2002; Voyich *et al*., 2003, 2004; Graham *et al*., 2005). Owing to space constraints, here we summarize the results from only one of these studies.

During the transition from a throat or skin infection to an invasive infection, GAS must adapt to changing environments and host factors. Recently, we used transcript profiling and functional analysis to investigate the transcriptome of a wild-type serotype M1 GAS strain in human blood (Graham *et al*., 2005). This was a particularly important investigation because GAS sepsis is a devastating infection with a high morbidity and mortality rate. Hence, insight into molecular events transpiring in blood was crucial. Using a custom-made high-density oligonucleotide array, we discovered that global changes in GAS gene expression occur rapidly in response to human blood exposure. Increased transcription was identified for many genes that are likely to enhance bacterial survival, including those encoding superantigens and host-evasion proteins. For example, upon blood exposure, we observed increased expression of GAS genes that interact with host cell surfaces (adhesions such as M1 protein, collagen-binding proteins, and capsule), and that contribute to the evasion of the host innate defenses (Sic, Mac, and SpeA). The analysis also provided new evidence that the CovR–CovS two-component gene-regulatory system functions to coordinate bacterial fitness attributes during disseminated host infections. This study provided crucial insights into strategies

used by a bacterial pathogen to thwart host defenses and survive in human blood, and suggested new vaccine and therapeutic strategies.

7. Summary

Genomic analysis of GAS has progressed substantially in the last three years, making it one of the more thoroughly analyzed human bacterial pathogens. Comparative genome sequence analysis has shown that prophages are the major source of variation in gene content among GAS strains. Genome sequencing also has identified many previously unknown virulence factors and genetic elements encoding drug resistance. Expression microarray analyses has revealed hitherto unknown regulatory pathways contributing to survival in response to temperature change and human polymorphonuclear leukocytes. Genome-wide analyses have significantly enhanced our understanding of the molecular basis underlying the emergence of new, highly successful GAS clones. Taken together, the results of these studies indicate that genomic analyses of GAS is an area of considerable interest and promises to yield additional contributions to our understanding of host–pathogen interactions and bacterial population genetics.

Short Specialist Review

Yersinia

Nicholas R. Thomson
The Wellcome Trust Sanger Institute, Cambridge, UK

1. Introduction

The genus *Yersinia* is composed of 11 species: *Y. pseudotuberculosis, Y, enterocolitica, Y. pestis, Y. intermedia, Y. kristensenii, Y. frederiksenii, Y. aldovae, Y. rohdei, Y. mollaretii, Y. bercovieri,* and *Y. ruckeri* (Sulakvelidze, 2000). Of the 11 species, only *Y. pseudotuberculosis, Y, enterocolitica*, and *Y. pestis* are pathogenic. There are several theories as to the evolution of these pathogenic strains but the favored notion is that they evolved from a nonpathogenic ancestor by the accretion of plasmids and chromosomally encoded genetic determinants.

Multilocus sequence analysis and DNA–DNA hybridization studies have shown that the pathogenic *Yersinia* are closely related: *Y. enterocolitica* and *Y. pseudotuberculosis* are thought to have diverged within the last 200 Myr and *Y. pestis* is a clone that has split from *Y. pseudotuberculosis* as recently as 1500 years ago and could in fact constitute a *Y. pseudotuberculosis* subspecies (Achtman *et al*., 1999; Bercovier *et al*., 1980).

Although the pathogenic *Yersinia* are genetically highly related, clinically they are clearly divided: *Y. pseudotuberculosis* and *Y. enterocolitica* are enteropathogens causing generally self-limiting gastroenteritis and infecting by the fecal-oral route. On the other hand, *Y. pestis* is primarily a rodent pathogen and is usually transmitted subcutaneously by the bite of an infected flea (principally *Xenopsylla cheopis*) and causes the often fatal bubonic plague, or upon infection of the lungs, causes pneumonic plague, in humans.

Thus, *Y. pestis* appears to be a species that has rapidly adapted from being a mammalian enteropathogen to an obligate bloodborne pathogen of mammals, which can also parasitize insects and utilize them as vectors for onward dissemination of infection (Achtman *et al*., 1999; Pepe and Miller, 1993). Historically, *Y. pestis* is thought to have been responsible for three human pandemics, the most infamous of which is The Black Death (fourteenth to nineteenth centuries). However, there is a current pandemic of plague that has seen recent outbreaks in Madagascar and Algeria and that claims an average of ∼2000 lives per annum (Titball and Williamson, 2001; WHO figures **http://www.who.int**).

Genetically it is clear that key evolutionary leaps in the emergence of these pathogenic *Yersinia* were made by the acquisition of a selection of virulence plasmids. All of the highly pathogenic yersiniae carry the 70-kb *Yersinia* virulence plasmid,

collectively known as the low calcium response (LCR) plasmid. Uniquely, *Y. pestis* also carries two other plasmids, pMT1 and pCD1 (discussed below; Table 1).

2. The *Yersinia* plasmids

The LCR plasmids from *Y. enterocolitica* (pYV), *Y. pestis* (pCD1), and *Y. pseudotuberculosis* (pIB1) all carry the highly characterized Yop virulon, which directs the production of a type III secretion system (TTSS), translocators, and secreted effector proteins, known as Yops (*Yersinia* outer proteins). The Yop virulon is essential for virulence of all the highly pathogenic yersinae in a variety of its hosts (for a review, see Brubaker, 1991 and Cornelis, 2002). The externally exposed portion of the TTSS apparatus appears as a needlelike structure, which penetrates the host cell membrane and facilitates the direct injection of the Yops from the bacterium into the eukaryotic host cell (Hoiczyk and Blobel, 2001). Once injected, Yops inhibit phagocytosis and block any proinflammatory response mounted by the host's immune cells. The organization of the Yop virulon is highly conserved amongst all the LCR plasmids, although there are some differences in the gross structure and organization of these plasmids, which can largely be explained by recombination and transposition associated with insertion sequence (IS) elements (Prentice *et al*., 2001; Hu *et al*., 1998).

The LCR plasmids also encode the *yadA* gene, which encodes an adhesin involved in mucus and epithelial cell attachment and invasion (Pepe and Miller, 1993; reviewed by El Tahir and Skurnik, 2001). The *yadA* gene is intact in the enteropathogenic *Yersinia,* but carries a frameshift mutation in *Y. pestis*. Moreover, complementation of the YadA phenotype in *Y. pestis* has been shown to result in a significant decrease in virulence by the subcutaneous infection route (Rosqvist *et al*., 1988).

Of the *Y. pestis* specific plasmids, three pMT1 plasmids (for murine toxin; also known as pFra (Fraction 1 antigen)) have been sequenced, ranging in size between 96 and 110 kb and predicted to encode between 78 and 115 genes (Parkhill *et al*., 2001b; Lindler *et al*., 1998; Hu *et al*., 1998) (Table 1). Like pYV, the variability in the size and gene order in different pMT1 plasmids is mainly a consequence of IS mediated recombination and/or deletion (Filippov *et al*., 1990; Prentice *et al*., 2001). Comparisons of pMT1 with other plasmids revealed that they share extensive regions of similarity with the cryptic *Salmonella enterica* serovar Typhi (*S*. Typhi) plasmid pHCM2 (>50% of pFra sharing >90% nucleotide identity with pHCM2; Prentice *et al*., 2001; Figure 1). This abnormally high level of sequence conservation between plasmids of *Y. pestis* and *S*. Typhi was thought to be indicative of recent horizontal exchange and led to the current notion that the immediate predecessor of *Y. pestis* acquired pMT1 following the coinfection of a common host, perhaps a rodent, with another enteropathogen, such as *S*. Typhi (Prentice *et al*., 2001).

Plasmid pMT1 carries several important virulence factors, the fraction 1 protective antigen and the *ymt* gene encoding the murine toxin. The fraction 1 antigen, while being strongly immunoprotective, is not a virulence factor (Friedlander *et al*.,

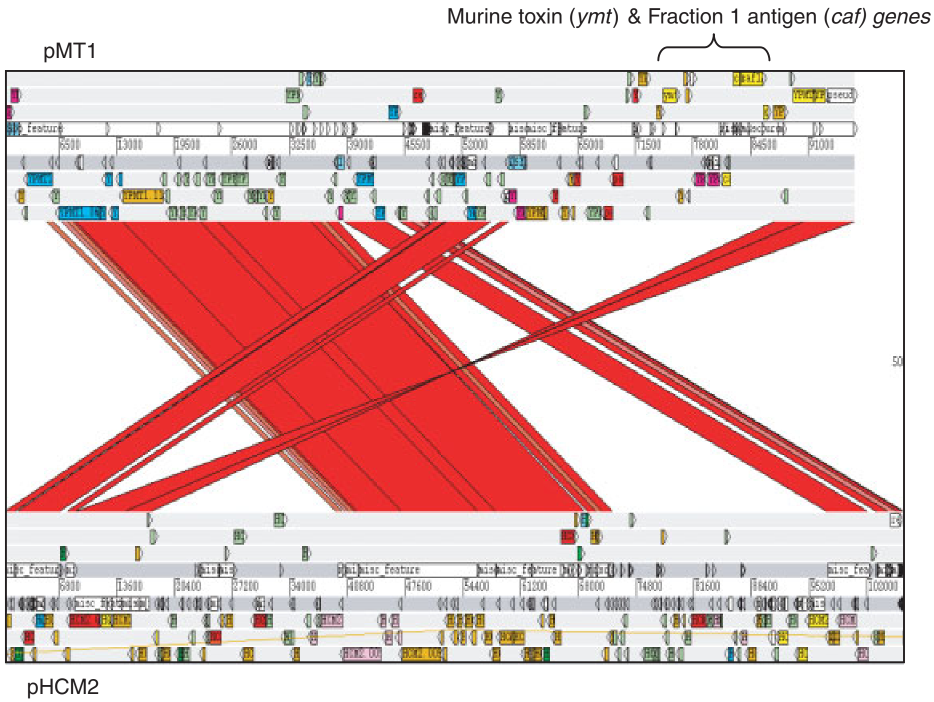

Figure 1 Global comparison between *Y. pestis* CO92 plasmid pMT1 and *S.* Typhi CT18 plasmid pHCM2. The figure shows DNA:DNA matches (computed using BLASTN and displayed using ACT **http://www.sanger.ac.uk/software/ACT**). The gray bars between the genomes represent individual BLASTN matches. Some of the shorter and weaker BLASTN matches have been removed to show the overall structure of the comparison

1995). Conversely, the *ymt* gene product is highly toxic in the mouse and rat models and was thought to be important for the high lethality of the plague in these hosts (Brown and Montie, 1977). However, isogenic *ymt* mutants do not significantly affect LD_{50} in mice. More recently, the gene product of *ymt* has been shown to have motifs in common with phospholipases and to be essential for *Y. pestis* to successfully colonize and survive within the flea midgut (Hinnebusch *et al*., 2000; Hinnebusch *et al*., 2002b).

At 9.6 kb, plasmid pPCP1 (also known as pPla and pPst) is the smallest of the three *Y. pestis* specific plasmids and predicted to encode 5/9 protein products (Parkhill *et al*., 2001b; Hu *et al*., 1998) (Table 1). These include pesticin (a pore-forming colicin) and pesticin immunity factor (Vollmer *et al*., 1997) as well as the plasminogen activator protein Pla. Pla is important for the systemic spread of plague within the mammalian host. It is a multifunctional protein, which gets its name from the ability to promote the maturation of the mammalian proenzyme plasminogen into plasmin (Beesley *et al*., 1967; Lahteenmaki *et al*., 1998; Lahteenmaki *et al*., 2001). The consequence of this is the bacterial-induced cleavage of host fibrin and extracellular matrices that limit the systemic dissemination of *Y. pestis* within the mammalian host. It has been suggested that pPCP1 was acquired after pMT1 and, since the midgut of the flea provides excellent opportunities for the acquisition of

horizontally transferred DNA (Hinnebusch *et al*., 2002a), this is where pPCP1 may have been acquired.

It has been known for sometime that while the pYV virulence plasmid of *Y. enterocolitica* is required for full virulence, there are other chromosomally located virulence factors that are also important (Heesemann and Laufs, 1984; Heesemann *et al*., 1984; Heesemann and Laufs, 1983). Some of these chromosomally encoded virulence determinants have been extensively studied such as *yst*, *inv*, and the hemin storage locus (see Revell and Miller, 2001 and references therein). However, compared to the depth of knowledge held for the plasmid encoded pathogenicity determinants, relatively little was known about the chromosome as a whole. This has been the impetus for the completed and ongoing whole genome sequencing projects.

3. The *Yersinia pestis* chromosome

Currently, two complete genome sequences are available: *Yersinia pestis* biovars Orientalis strain CO92 (CO92) (isolated from a fatal human case of primary pneumonic plague; Parkhill *et al*., 2001b) and Mediaevalis strain KIM10+ (KIM), (a genetically amenable laboratory strain; Deng *et al*., 2002). However, there are also sequencing projects for another biovar of *Y. pestis* biovar Mediaevalis strain 91001 (The Institute of Microbiology and Epidemiology [China] AE017042), as well as *Y. pseudotuberculosis* strain IP32953 (Lawrence Livermore (USA)/Institute Pasteur (France)) and *Y. enterocolitica* strain 8081 (Sanger Institute (UK)).

The genomes of CO92 and KIM are very similar in size consisting of a 4 600 755-bp and a 4 653 728-bp chromosome, respectively (Table 1). Whole-genome analysis of the two sequenced *Y. pestis* genomes revealed extensive evidence of recent intragenomic rearrangements, which clearly distinguished the two different *Y. pestis* biovars (Figure 2; Deng *et al*., 2002; Parkhill *et al*., 2001b).

Comparisons with more distant enterobacterial relatives revealed that much of the apparent colinearity preserved between, for example, *Escherichia coli* K12 and *S.* Typhi had been lost by these two yersiniae (Figure 2). However, if the relative distances of orthologous genes from the origins in *E. coli* and *Y. pestis* are compared, then there is a surprisingly high level of conservation. On the basis of these data, it was estimated that almost 50% of the core genes of KIM had been subject to interreplichore inversions during the evolution of the species (Deng *et al*., 2003). Many of these inversions are thought to be associated with recombination between IS elements. Although they are likely to have been important, the precise effects of these rearrangements on the biology and pathogenicity of *Y. pestis* remains unclear.

4. Genome contents

The genome contents of KIM and CO92 are also highly similar. Of the total genes predicted for each genome (4090 for KIM and 4016 for CO92), 3672 were common to both. The most significant differences in gene content between these genomes

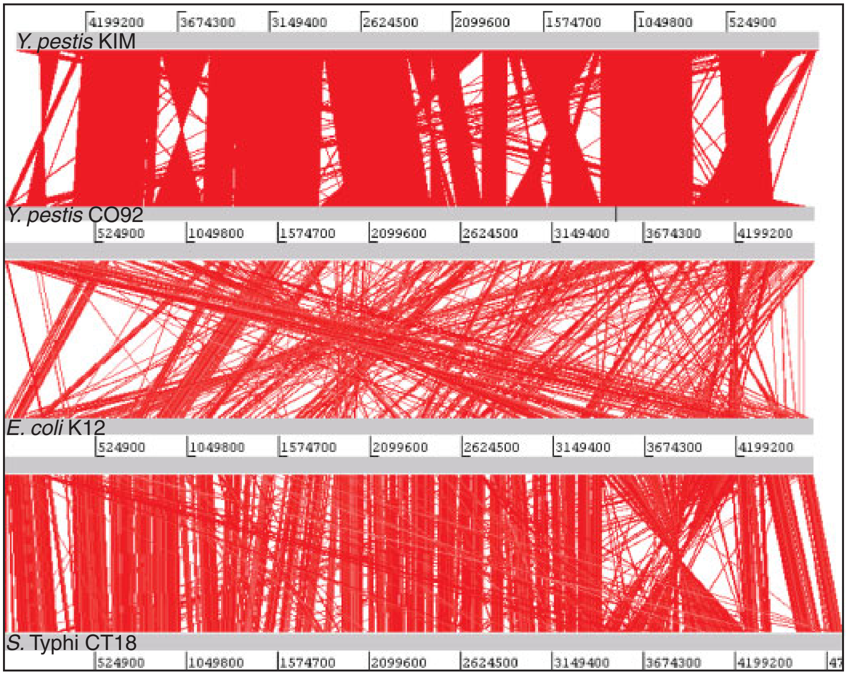

Figure 2 Global comparison between *Y. pestis* KIM, *Y. pestis* CO92, *E. coli* K12, and *S.* Typhi CT18. The figure shows six frame translated DNA:translated DNA matches (computed using TBLASTX and displayed using ACT **http://www.sanger.ac.uk/software/ACT**) pairwise between the four enterobacterial genomes. The genomes are, from the top down, *Y. pestis* KIM, *Y. pestis* CO92, *E. coli* K12, and *S.* Typhi CT18. The red bars between the genomes represent individual TBLASTX matches. Some of the shorter and weaker TBLASTX matches have been removed to show the overall structure of the comparison

included an extra rRNA operon in KIM and the loss of many flagella-related genes from KIM, many of which remain intact in CO92 (>80 genes). Other genomic differences were represented by an expanded population of IS elements in CO92 (140 vs. 122 complete or partial IS elements for CO92 and KIM, respectively) and an integrated prophage absent from KIM.

5. Pathogenicity islands/laterally acquired DNA

Pathogenicity Islands (PAI), first described by Hacker *et al.* (1997), are a phenomenon common to many enteric pathogens and the yersiniae are no exception. The genome sequences of the two *Y. pestis* biovars revealed a large number of regions displaying many of the characteristics of PAIs. These included those encoding genes that were involved in iron uptake as well as those encoding homologs of high–molecular weight insecticidal toxins and viral enhancins (Waterfield *et al.*, 2001). However, some of the *Y. pestis* insect toxin genes were found to carry frameshift mutations and so it is not clear whether these genes are simply vestiges of a former pathogenic association with an insect host.

In addition to the highly characterized plasmid-borne type III secretion system (Yop; see above), a second novel TTSS was discovered within a potential PAI on the *Y. pestis* genome. This novel system was remarkably similar to the TTSS located on *Salmonella* pathogenicity island 2 (SPI-2) and, like that of SPI-2, may act at different stages in the infection process to the plasmid-borne system.

6. Gene decay and genetic streamlining

The genomes of *Y. pestis* carry a large number of pseudogenes amounting to ∼4% of the total gene complement. The presence of significant numbers of pseudogenes and expansion of IS elements have been seen in other recently emerged pathogens (Cole *et al*., 2001; Andersson *et al*., 1998; Parkhill *et al*., 2001a; Parkhill *et al*., 2003) where genes required solely for the former lifestyle are lost in the process of phenotypic streamlining.

Most of the *Y. pestis* pseudogenes were associated with pathogenicity and/or predicted to encode surface-exposed proteins. Examples include the *iucA*, a gene essential for the production of aerobactin, several flagella biosynthetic genes, and many genes involved in lipopolysaccharide (LPS) biosynthesis important in *Y. enterocolitica* for resistance to complement-mediated and phagocyte killing (Darwin and Miller, 1999).

Mutations in energy metabolism and central and intermediary metabolism were underrepresented in the *Y. pestis* genome. Examples of pseudogenes in this class include those involved in glycerol fermentation. Genes *glpD*, *glpK*, and *glpX* are intact in biovar Medievalis (KIM) but have been subject to deletion events in biovar Orientalis (CO92), and this is the genetic explanation for the phenotype that is used to distinguish the two biovars (Parkhill *et al*., 2001b; Deng *et al*., 2002).

What is clear from the genomes of *Y. pestis* is that there has been significant gene loss as well as gain and that in combination with the extensive genome rearrangements observed, they are all likely to have been significant in the evolution of this acute pathogen. Combined with what we already know about the chromosome and extrachromosomal elements of the other *Yersinia*, it is clear that many of these determinants have been acquired incrementally during the evolution of this pathogen, possibly as an antecedent to speciation. The completion of the ongoing *Yersinia* genome projects should allow for a more complete analysis of the changes that occurred preceding the emergence of these pathogens, new and old.

The genomes of *Y. pestis* strain 91001 and *Y. pseudotuberculosis* strain IP32953 have now been published and offer further fascinating insights into the yersiniae (Chain *et al*., 2004 and Song *et al*., 2004).

Short Specialist Review

Chlamydiae

Timothy D. Read
Biological Defense Research Directorate, Naval Medical Research Center, Rockville, MD, USA

1. Introduction

The chlamydiae are a distinct group of gram-negative bacteria restricted to growth within a specialized vacuole of eukaryotic cells. Chlamydiae have a biphasic life cycle, with a metabolically dormant, infectious "elementary body" (EB) and a replicative form (reticulate body; RB) that is restricted to an intracellular vacuole (Rockey and Matsumoto, 1999). Members of the genus *Chlamydiaceae* include important human and animal pathogens, notably *Chlamydia trachomatis*, a common agent of ocular trachoma and sexually transmitted disease, and *Chlamydia pneumoniae*, frequently a cause of community acquired lung infections in humans, which has also been linked to atherosclerosis. It is becoming apparent from 16 S RNA sequencing studies (*see* Article 6, **The genetic structure of human pathogens**, Volume 1) that the *Chlamydiaceae* are members of a very diverse class of organisms, the Chlamydiales, ubiquitous in nature (Ossewaarde and Meijer, 1999). Owing to the difficulties inherent in experimental work on an organism that must be cultured within eukaryotic cells and has no convenient system for genetics, the advent of genome sequencing has had an immense impact on understanding chlamydiae biology.

At present, there are six published complete chlamydiae sequence (Table 1). The three *C. pneumoniae* genomes are almost identical, with only a few hundred polymorphisms over 1.23 Mb genomes (Daugaard *et al*., 2001), reflecting the probable very recent worldwide clonal spread of the organism. *Chlamydia pneumoniae* and *Chlamydia caviae* are members of the *Chlamydophila* branch of Chlamydiaceae (Everett *et al*., 1999), approximately 200 kb larger than the Chlamydia genomes (Table 1). A conserved small plasmid (Thomas *et al*., 1997) was present in all genomes sequenced but *C. pneumoniae*. *Chlamydia pneumoniae* AR39 contained the replicative form of a bacteriophage of the microvirus family (Read *et al*., 2000).

2. Genome architecture

Chlamydiae genomes are reduced in size compared to those of free-living bacteria, which are typically > 2.5 Mb. However, there is no evidence of the recent genome

Table 1 Features of published chlamydiaceae genomes sequences (April 2004)

degradation seen as the accumulation of genomic repeats and pseudogenes in other obligate pathogens such as *Mycobacterium leprae* (*see* Article 52, **Genomics of the *Mycobacterium tuberculosis* complex and *Mycobacterium leprae***, Volume 4) or *Rickettsia prowazaki*. The completed chlamydiae genomes lack mobile genetics elements such as prophages and insertion sequences. There are no regions in the genome with unusually high or low percent GC sequence or atypical dinucleotide composition (*see* Article 66, **Methods for detecting horizontal transfer of genes**, Volume 4), which suggest the presence of pathogenicity islands (*see* Article 66, **Methods for detecting horizontal transfer of genes**, Volume 4), or other recent acquisition of genes by horizontal transfer. Differences between species appear to be localized to the region of the genome near the predicted DNA replication termination locus that has been termed the *plasticity zone*. While there are no true prophages, it does appear that portions of microvirus sequence have been integrated in this area of the *C. caviae* and *C. pneumoniae* genomes, presumably by illegitimate recombination. As in other bacteria, the replication origin and termination regions appear to be the focus of large symmetrical inversions (Suyama and Bork, 2001). Using these inversions as a molecular clock, it seems that there is an unusually high degree of nucleotide sequence divergence compared to other groups of bacteria. This may be due to an elevated mutation rate, although chlamydiae genomes appear to contain most common bacteria DNA repair systems.

3. Common functions in chlamydia genomes

Genome sequencing was a bounding leap forward in basic understanding of the chlamydial cell. Chlamydiae were found not to be strict “energy parasites” (Moulder, 1991), but instead encoded most of the enzymes for aerobic metabolism via glycolysis and tricarboxylic acid cycle (TCA) cycle (McClarty, 1999; Stephens *et al*., 1998). The partial TCA cycle can be rescued by uptake of glutamate from

the intracellular environment (McClarty, 1999). There are also genes encoding respiratory chain components for the reoxidation of reduced cofactors produced by the TCA cycle. The genomes contains V-ATPase complex enzyme genes found in eukaryotes and plastids rather than the usual F-type ATPases seen in other bacteria (McClarty, 1999). Chlamydiae are able to import ATP from the host cell via an ADP/ATP transporter also found in Rickettsiae and plant genomes. All genomes also contain a paralagous gene that acts a general NTP importer. Chlamydiae contain all the genes necessary for glycogen synthesis, which may be an important energy store for the dormant EB phase. Like several other intracellular pathogens, Chlamydiae have a reduced component of membrane transport proteins compared to free-living organisms (Paulsen *et al*., 2001). There is a preponderance of transporters involved in peptide and amino-acid import, reflecting the reduced capacity for de novo biosynthesis of these molecules.

Type III secretion system (*see* Article 49, **Bacterial pathogens of man**, Volume 4) genes are conserved in all chlamydiae genomes, reflecting their importance in interactions with the host. Aside from the previously identified major outer membrane protein, genome sequencing also revealed a complex multigene family of polymorphic outer membrane proteins (Pmps) that vary in number from 9 (*C. trachomatis*) to 21 (*C. pneumoniae*). These proteins have been localized to the surface of the RB and may play roles in adhesion and cell signaling.

Chlamydiae tend to be deeply separated from other bacteria in phylogenetic trees constructed with common conserved proteins. This reflects an enduring ecological and genetic isolation as an intracellular pathogen over many millions of years. The fact that many chlamydial proteins group with cyanobacterial, plastid, or plant sequences in evolutionary reconstructions suggests that the chlamydiae may have had their most common bacterial ancestor with the organisms that went on to form endosymbiotic relationships with plant cells (Brinkman *et al*., 2002).

4. Species and strain-specific genes

Despite their relative genome simplicity the chlamydiae cause a wide variety of different conditions over a broad range of vertebrate hosts. This may be surprising, considering two-thirds to three-quarters of the genes may be necessary for basic cellular propagation since they are conserved in all genomes (Read *et al*., 2003). The genes that are specific to individual species and strains (many of which are located in the plasticity zone) (Read *et al*., 2000) may offer clues about how tropisms occur. One constant theme in the sequenced genomes is a differing capacity for overcoming the almost complete lack of nucleotide biosynthetic genes by salvaging precursors from the cell environment. In this regard, there is strong evidence of lateral gene transfer of nucleotide salvage genes between the *Chlamydia* and *Chlamydophila* branches of the Chlamydiaceae (Read *et al*., 2003) Another theme is differences in capacity to catabolize the amino acid tryptophan: *C. caviae* has genes encoding an almost complete biosynthetic pathway, whereas *C. pneumoniae*, a highly successful human pathogen, has none (Read *et al*., 2000, 2003). The proinflammatory cytokine γ-interferon can lead to restriction of intracellular tryptophan levels. McClarty and colleagues have shown how even

the presence of a partial tryptophan biosynthesis cluster in *C. trachomatis* (Wood *et al*., 2003) may aid the cell in avoiding the effects of γ-interferon expression. Other notable strain-specific genes include a large toxin-like determinant, related in amino-acid sequence to an *Escherichia coli* O157:H7 protein (*see* Article 51, **Genomics of enterobacteriaceae**, Volume 4) (Read *et al*., 2000), found in *C. caviae* and *C. muridarum,* and a gene in *C. caviae* that encodes an invasin-like protein (Read *et al*., 2003). Some difference between strains may be effected by changes as subtle as gene duplication or single nucleotide polymorphisms (Belland *et al*., 2001).

5. Future directions

There are several chlamydiae genome projects ongoing, both within the *Chlamydiaceae* and also *Simkania* and *Parachlamydia*, genera that represent the vast undersampled diversity of the group. Sequencing enables functional genomics, for example, studying gene expression during cell differentiation using whole-genome microarrays (Nicholson *et al*., 2003) (*see* Article 94, **Expression and localization of proteins in mammalian cells**, Volume 4). Genome sequencing will likely be a driving force for discovery in the continuing absence of genetic methods in the group, and the future of chlamydiae research will be increasingly driven by questions discovered through various type of genomic analysis.

Short Specialist Review

Spirochete genomes

George Weinstock
Baylor College of Medicine, Houston, TX, USA

Spirochetes are bacteria originally defined as a distinct group based on their distinct morphology. Spirochetes appear as long threadlike spiral-shaped organisms in the microscope. Subsequent classification based on sequence typing with rRNA sequences confirmed this grouping, making the spirochetes the only bacteria to be correctly classified on the basis of morphological criteria. Spirochetes can be highly motile but their flagellar apparatus is located in the periplasm, unlike most other bacteria that have externally located flagella. Their body shape is believed to help them maintain high motility even in viscous environments, where they can "corkscrew" through the medium. Spirochetes are ubiquitous in the environment as well as within hosts, both as commensals as well as pathogenic invaders. In humans, commensal spirochetes are readily found in the mouth, for example. Some of the more well known spirochetes are *Treponema pallidum*, causative agent of syphilis, and *Borrelia burgdorferi*, the bacterium that causes Lyme disease (*see* Article 49, **Bacterial pathogens of man**, Volume 4).

A number of spirochete genomes have been sequenced (*see* Article 6, **The genetic structure of human pathogens**, Volume 1) including *T. pallidum* (1.1 Mb) (Fraser *et al*., 1998), *B. burgdorferi* (1.2 Mb) (Fraser *et al*., 1997), *Treponema denticola* (2.8 Mb) (Seshadri *et al*., 2004), and *Leptospira interrogans* (4.6 Mb) (Ren *et al*., 2003; Nascimento *et al*., 2004), while numerous other spirochete genome projects are in progress. Spirochetes are a discrete branch of the Eubacterial tree (*see* Article 40, **The domains of life and their evolutionary implications**, Volume 7, Article 44, **Phylogenomic approaches to bacterial phylogeny**, Volume 7, and Article 45, **Phylogenomics for studies of microbial evolution**, Volume 7), and are distinct from many of the other disease-causing organisms that have been targets for genome sequencing, such as bacteria from the Proteobacteria or gram-positive bacteria branches. In addition, some spirochetes, such as *T. pallidum*, live in very specific niches and do not appear to have undergone much genetic exchange with other bacteria. Because of this separation, spirochete genomes tend to contain spirochete-specific genes (e.g., for virulence factors) in addition to core genes found in all bacteria, such as genes for the flow of genetic information or for metabolic pathways that are broadly distributed (e.g., glycolysis).

T. pallidum was one of the first genome projects undertaken, starting in 1991 with the publication of the sequence in 1998 (Fraser *et al*., 1998). Because this organism is one of the last of the major pathogens that cannot be cultured in

the laboratory (it must be grown in rabbit testes), the genome sequence was deemed the best way to understand the molecular biology of syphilis, and the impact of the genome project has been significant. The *T. pallidum* genome is a single circular DNA molecule. It does not contain any recognizable prophages, translocatable elements, plasmids, or other remnants of horizontal gene transfer. Of the 1031 predicted protein-coding genes, about 40% either have no database match or only match sequences of unknown function from other organisms. However, a number of treponeme-specific gene families were discovered from the genome sequence, and these appear to include genes coding for virulence factors of this organism. Moreover, the sequence showed that *T. pallidum* has a limited repertoire of metabolic pathways, a consequence of the limited biological niche in which it lives (it only lives in humans with no external reservoir), and which may contribute to the difficulty in culturing the organism outside of its host. As a follow-up to the sequencing of this genome, each predicted protein-coding gene was individually cloned in *Escherichia coli* to produce each protein in this surrogate host (McKevitt *et al*., 2003). This clone set was used to identify all antigenic proteins following infections of rabbits or humans. A total of 106 antigenic proteins were found, about 10% of the proteome, and these were highly enriched for proteins that were predicted to be exported from the cytoplasm.

The *T. pallidum* strain that was sequenced was the Nichols strain of *T. pallidum* subsp. *pallidum*, the syphilis causing subspecies of *T. pallidum*. Several other subspecies exist that cause distinct diseases. Like the syphilis strain, none of these other subspecies can be cultured in the laboratory, and DNA–DNA hybridization showed the genomes to be more than 95% identical. One of these, *T. pallidum* subsp. *pertenue* (Gauthier strain), causes the tropical disease yaws and has been compared to the syphilis strain in detail. While yaws is distinct from syphilis (it is an invasive skin disease that is not sexually transmitted), the differences in gene content of the two genomes is limited to only a few genes, with no major differences such as the presence or absence of pathogenicity islands. In addition, there are less than 300 single nucleotide polymorphisms, out of over one million bases, so the differences between these organisms, leading to their different disease phenotypes, appear to be quite subtle.

A second treponeme whose genome has been sequenced is *T. denticola* (Seshadri *et al*., 2004). *T. denticola* is a resident of the oral cavity and is associated with periodontal and gingival diseases. It is a component of the biofilm that forms on teeth and interacts with other genera of bacteria in the mouth. It is one of a number of spirochetes that colonize the mouth and appear to be a part of the normal human flora. *T. denticola*, while in the same genus as *T. pallidum*, is quite different at both the genotypic and phenotypic levels. Its genome size is nearly three times that of *T. pallidum* and its G+C content is much lower. *T. denticola* has a more substantial metabolic capability than *T. pallidum* and can be cultured in the laboratory. Its genome also shows considerable evidence of horizontal gene transfer and contains a high content of repeated sequences. Most notable about *T. denticola* is that it has the largest number of predicted transporters of any bacterial genome. This, plus its metabolic capabilities, presumably allows it to compete favorably with other organisms in a range of environments.

B. burgdorferi has one of the most unusual prokaryotic genomes with its major chromosome being a linear molecule complete with telomeric ends, as well as dozens of linear and circular plasmids, some of which contain genes to enhance growth and infection and which are therefore not simply accessories (Fraser *et al*., 1997; Casjens *et al*., 2000). The number of these plasmids varies somewhat from strain to strain. This remarkable genome must have a curious origin and a novel selection for its maintenance. One notable observation is the presence of homologs of the *E. coli recBCD* recombination genes in *B. burgdorferi*. This system has not been widely found among bacterial genomes that have been sequenced, although in *E. coli* and its relatives it is a major system for DNA repair and homologous recombination. The presence of this recombination system may imply a unique DNA metabolism in *B. burgdorferi* compared to other spirochetes.

Leptospira interrogans is a spirochete that is broadly found in the environment and in animals, including humans. It is the cause of the zoonotic infection leptospirosis. It is carried by a number of animals, and frequently colonizes rats without causing disease. Two strains of *L. interrogans* have been sequenced (Ren *et al*., 2003; Nascimento *et al*., 2004) and the reveal a complex genome as expected for an organism with such a broad biological niche.

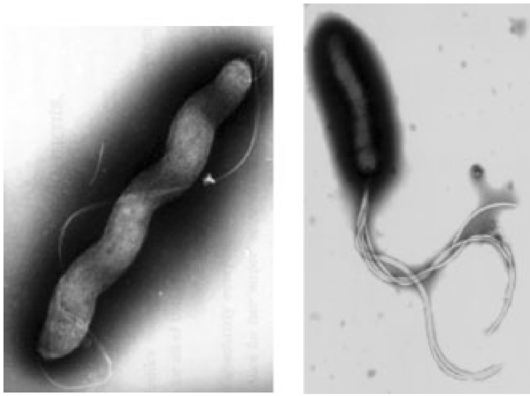
Short Specialist Review

Comparative genomics of the ε-proteobacterial human pathogens *Helicobacter pylori* and *Campylobacter jejuni*

Nick Dorrell and Brendan Wren
London School of Hygiene & Tropical Medicine, London, UK

1. Introduction



Helicobacter pylori and *Campylobacter jejuni* are among the most common bacterial pathogens encountered by humans. Infection with *H. pylori* can cause gastritis and ulceration, and it can be found in the stomach of half the world's population, whereas *C. jejuni* is the most frequently identified gastrointestinal pathogen and is one of the most common causes of diarrhoeal disease. Both pathogens can cause serious postinfection sequalae, with *H. pylori* being responsible for some forms of gastric cancer and *C. jejuni* causing neuromuscular diseases such as Guillian–Barré syndrome. Another curiosity is that despite the prevalence and importance of the diseases caused by *H. pylori* and *C. jejuni*, they have only been recognized as human pathogens within the last 25 years.

At the genetic, metabolic, and morphological levels, they share many common characteristics. *H. pylori* and *C. jejuni* are both members of the ε-proteobacteria subdivision of eubacteria. They are microaerophilic, spiral shaped, and motile, residing in the mucosa of their hosts (Figure 1). In fact, when *H. pylori* was first identified in 1983, it was classified in the *Campylobacter* genus. However, closer inspection confirms that they are from distinct genuses and have different primary hosts. *H. pylori* is a human-specific pathogen, whereas humans are an accidental part of the life cycle of *C. jejuni*, which are normally found as a commensal in the avian crop. *Campylobacter jejuni* can also survive in aquatic environments.

How can the availability of the genome sequences and subsequent genomic studies help explain the genetic, ecological, and pathogenic similarities and differences between these two major pathogens?

2. Common genome characteristics

H. pylori (26695) and *C. jejuni* (NCTC11168) were among the first microorganisms to be fully sequenced (Parkhill *et al.*, 2000; Tomb *et al.*, 1997), and

Campylobacter jejuni *Helicobacter pylori*

Figure 1 The rogues gallery – electron microscope pictures of the two organisms

indeed *H. pylori* was the first bacterium for which the genome of a second strain was determined (Alm *et al*., 1999). The 26695 and NCTC11168 genomes are of relatively small size and have similar GC content (1.67 Mb and 1.64 Mb and 39% and 30.6% respectively). Forty-eight percent of their predicted protein-coding sequences (CDSs) are orthologous (>30% similarity). These include CDSs involved in general housekeeping functions, metabolism, respiration, chemotaxis, and motility. Other similarities were the general lack of regulatory genes, including only three sigma factors and few two component regulatory systems. The CDSs are frequently found in linked groups transcribed in the same direction (Figure 2), but CDSs of an expected related function often appear to be scattered across the genome, with a general lack of operon structure (e.g., genes involved in flagella biogenesis). Close inspection of the nucleotide sequences of both genomes identified dozens of homopolymeric tracts or dinucleotide repeats characteristic of regions of slip strand mispairing. This results in phase variable proteins often involved in the biosynthesis of surface structures. Such repeats may be considered as a primordial mechanism that some mucosal pathogens with small genomes use to hugely vary their surface structure. Subsequent studies have confirmed that these phase variable genes are an important feature for the respective life cycles of both *H. pylori* and *C. jejuni* (Appelmelk *et al*., 1998; Linton *et al*., 2000).

3. What is in and what is out

The complete genome sequences of *H. pylori* and *C. jejuni* allow direct comparison of their genome complements and the opportunity to relate the presence and absence of sets of genes to the respective lifestyles of these pathogens. In the case of *H. pylori*, it is a human-specific pathogen that resides in the acidic environment of the stomach and interacts directly with gastric epithelial cells. These characteristics are reflected by the presence of the urease locus that allows the organism to survive at low pH and the *cag* pathogenicity island, encoding a type IV secretion system

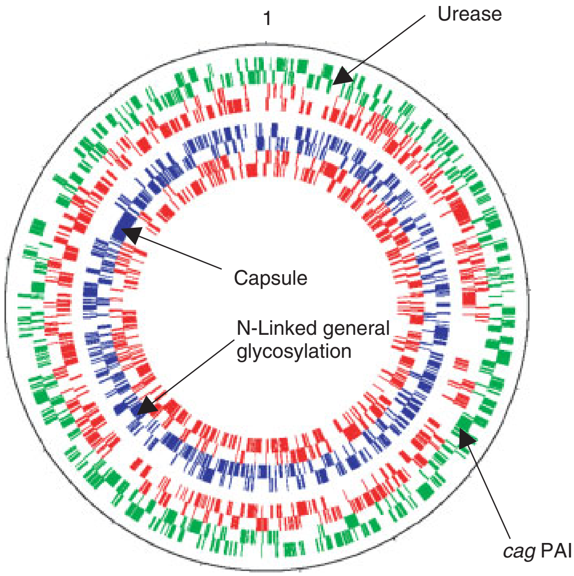


Figure 2 Genome comparison of *Helicobacter pylori* 26695 and *Campylobacter jejuni* NCTC11168. The outer four circles represent the *H. pylori*-predicted protein-coding sequences on both the plus and minus strands; green indicates *H. pylori* unique genes and red indicates genes shared with *C. jejuni*. The urease locus and *cag* pathogenicity island are highlighted. The inner four circles represent the *C. jejuni*-predicted protein-coding sequences on both the plus and minus strands; blue indicates *C. jejuni* unique genes and red indicates genes shared with *H. pylori*. The capsule biosynthesis locus and *N*-linked general glycosylation locus are highlighted

that is involved in interactions between *H. pylori* and gastric epithelial cells. These loci are absent from the *C. jejuni* NCTC11168 genome (Figure 2). By contrast, the *C. jejuni* genome has a capsule locus and an *N*-linked general glycosylation pathway, both features absent in *H. pylori* 26695 (Figure 2) and unknown prior to the commencement of the genome project. Subsequently, a noncapsulated mutant was shown to have reduced ability to adhere to and invade intestinal epithelial cells and also reduced virulence in the ferret model of diarrhoeal disease (Bacon *et al*., 2001). The *N*-linked general glycosylation pathway modifies over 30 *C. jejuni* proteins, with a heptasaccharide (Young *et al*., 2002). The purpose of this modification is unknown, but it is speculated that it may be important in suppressing the immune response in avians to maintain its commensal status. *Campylobacter jejuni* appears to possess a greater metabolic and regulatory versatility than *H. pylori*, probably reflecting the very restricted niche of the human stomach where the latter is found and the more diverse environments in which the former can grow (Kelly, 2001).

4. Postgenome studies

Because *H. pylori* and *C. jejuni* were among the first organisms to be sequenced, they have been well studied in the postgenome **era**. Further representatives of these

species have been, or are being sequenced. Whole-genome comparison studies using microarrays (Article 98, **Bacterial genome organization: comparative expression profiling, operons, regulons, and beyond**, Volume 4) have shown both species to be diverse with less than 80% of the respective genomes representing functional core or species-specific genes (Dorrell *et al*., 2001; Salama *et al*., 2000). Several transcriptome studies (*see* Article 93, **Microarray CGH**, Volume 4) have been performed examining the organisms under a range of stress- and host-related environments. Proteome maps are available for both organisms, and a comprehensive protein–protein interaction map has been published for *H. pylori* (Rain *et al*., 2001).

5. Further sequenced ε-proteobacteria

More recently, further members of the ε-proteobacteria have been sequenced. *Helicobacter hepaticus* is most similar to *H. pylori,* but crucially lacks the *Cag* pathogenicity island and the urease operon, as may be expected, as *H. hepaticus* does not reside in the human stomach but in the small intestine (Suerbaum *et al*., 2003). In fact, some *H. hepaticus* metabolic genes most closely resemble those in *C. jejuni*, suggesting some form of environmental adaptation as both organisms reside in the intestine. *Wollinella succinogenes* represents a halfway house between *H. pylori* and *C. jejuni*, with some features from each of the organisms (Baar *et al*., 2003). By contrast to *H. pylori* and *C. jejuni*, *W. succinogenes* has an enormous range of regulatory genes, with the highest percentage of genes in any genome coding for histidine kinases or their cognate regulators. This feature may reflect the broad range of environments in which this bacterium is known to survive.

6. Conclusions

Ironically, although *H. pylori* and *C. jejuni* are relatively recently identified human pathogens, they are now among the most comprehensively studied. Helicobacteriologists and campylobacteriologists have truly benefited from the postgenome bonanza and this has increased our understanding of the dynamic and complex interplay between these pathogens and their respective hosts. The emphasis now must be to convert this new-found knowledge into appropriate intervention strategies to reduce the burden of these two problematic pathogens on human health.

Short Specialist Review

The neisserial genomes: what they reveal about the diversity and behavior of these species

Nigel J. Saunders and Lori A. S. Snyder
University of Oxford, Oxford, UK

The human pathogens *Neisseria meningitidis* and *Neisseria gonorrhoeae* are closely related organisms, with high sequence identity (typically greater than 95%) between their common genes, yet the diseases they cause are vastly different. *N. meningitidis* normally exists as a harmless commensal in the human nasopharynx, but when it becomes invasive it causes bacterial meningitis and severe septicaemia, which are both life threatening even with prompt and appropriate antibiotic treatment. *N. gonorrhoeae*, on the other hand, almost always causes disease following colonization, although gonorrhoea infections can be asymptomatic, particularly in women. Gonococcal infection is normally limited to epithelial surfaces but can ascend the female reproductive tract, leading to fertility-threatening pelvic inflammatory disease, and can also cause blindness following eye infection of vaginally delivered infants. *N. gonorrhoeae* can, untypically, cause disseminated infections including arthritis and a septicaemic infection, but these are much less severe than the disseminated meningococcal infections.

Since a genome sequence is a single time-point snapshot of a subculture, of a strain, of a species of bacteria, it is inherently an example of a bacterial system rather than a representative of the whole species. Fortunately, as more related bacterial genomes are sequenced, this provides a wider context in which to interpret these individual snapshots. With multiple genome sequences, comparative analyses are possible, which can be usefully linked to existing experimentally derived information for the species. In this way, a much deeper and more complete picture of a species' evolutionary and functional behavior can be perceived. To date, there are two complete and published (Parkhill *et al*., 2000; Tettelin *et al*., 2000) and one complete and publicly available (Sanger Institute) *N. meningitidis* genome sequences, and one *N. gonorrhoeae* genome sequence (currently unpublished from ACGT-OU), which together are far more informative than any single sequence could be alone.

Because of their medical importance, the *Neisseria* spp. have been studied intensely since the discovery of the gonococcus toward the end of the nineteenth Century (Neisser, 1879). The results of these studies can be drawn upon, tested against, and reconsidered in the light of the complete genome sequences. The genome

sequences, therefore, in the context of the other information available, provide an important framework for understanding their biology from a whole-system perspective, and are key to the design and construction of future experiments.

Considering the available information as a whole, and the features that are apparent from study of the genome sequences, the most striking general feature of these species is that, above all, they are capable of great change and flexibility. Although it may initially seem counterintuitive, the "static" genome sequences provide many indications of the "dynamic" nature of these species. They are models of a very different paradigm of bacterial evolution and function to those presented by the "classical model bacterial systems" such as *Escherichia coli* and *Bacillus subtilis* in that they have evolved a very different strategy for adapting to changing environmental conditions founded upon rapid evolutionary principals rather than upon the stable maintenance of highly specialized, tightly regulated, systems. However, this should not lead to a conclusion that they are untypical of bacterial systems as a whole. Indeed, they may be usefully considered representative of many other species with similar evolutionary and adaptive strategies, including, for example, *Haemophilus*, *Helicobacter*, *Campylobacter*, and *Bordetella* species groups.

The *Neisseria* spp. are known to have relatively panmictic population structures owing to frequent intraspecies recombination events (Smith *et al*., 1993; Feil *et al*., 1999; Holmes *et al*., 1999) facilitated by a common uptake signal sequence (Goodman and Scocca, 1988; Elkins *et al*., 1991). Despite this context, genome-level comparisons of the gene complements generated some initially surprising results. The strain MC58 and Z2491 meningococcal genome sequences are approximately as divergent from one another, as the meningococcal strain MC58 is from gonococcal strain FA1090. This variability in the gene complements of the genome sequences makes the task of identifying the genes that differentiate the meningococci and their behavior and host interactions from the gonococci a large and complex task.

On the basis of the pool of currently annotated features, each neisserial genome contains between 67 and 183 unique genes that are not present in the other three genome sequences. Comparison of the gene complements of all of the meningococcal genome sequences with the single gonococcal sequence identifies 645 differences in the presence of genes, but some of these differences are specific to the gonococcal strain used in genome sequencing, as shown by comparisons with the other main experimental strains using microarray-based comparative genome hybridization (Snyder *et al*., 2004).

Probably the longest recognized differentiating characteristic between *N. meningitidis* and *N. gonorrhoeae* is the presence of the meningococcal capsule. The genes responsible for the possession of a polysaccharide capsule by the meningococci are believed to have been horizontally acquired either after or as part of the speciation split between these pathogens. Differences between the type of capsule produced are due to gene complement differences at the capsule gene locus, a locus that is devoid of all capsule-associated genes in the gonococcus, in the nonpathogenic *N. lactamica*, and some noninvasive strains of *N. meningitidis* (Claus *et al*., 2002; Dolan-Livengood *et al*., 2003). However, the differences between these species are clearly far deeper and more complex, and it should not be assumed that the gonococcus would behave similarly to the meningococcus, simply following acquisition

of a capsule, or that an acapsulate meningococcus behaves in a gonococcal fashion. Getting to the heart of this subject is likely to depend upon extensive comparative studies addressing many strains, and should be greatly assisted by the other neisserial sequencing projects currently underway, particularly that of *N. lactamica* (Sanger Institute).

Some conserved genes flank other genes, or groups of genes, that differ between the sequenced strains. These genes have been recognized to be mobile, and exist in different combinations in different strains. These locations have been defined as "Minimal Mobile Elements" (MMEs) and are characterized as sites in which strain-specific genes are preferentially located between flanking genes with conserved sequence and chromosomal organization, such that these flanking regions can serve as substrates for homologous recombination following natural transformation. The first of the regions to be studied in an extended set of strains, between the *pheS* and *pheT* genes of the *Neisseria* spp., contains seven different genes or combinations of genes between the conserved flanking sequences (Saunders and Snyder, 2002). There are many more such regions that are currently under investigation and this will certainly lead to the identification of new neisserial genes, and to a better picture of strain differentiating characteristics. This is a good example of how the study of genomes from a limited number of strains can be extended into analysis of the wider bacterial population.

The capacity for adaptive change mediated by changes at the DNA level in these species resides within individual strains as well as being a product of genetic exchange between different organisms. The neisserial silent and expressed pilus system is well known and has been a teaching paradigm for many years (Haas *et al*., 1992). Two additional silent and expressed cassette systems have been proposed following assessments of the genome sequences, which reveal the way in which the study of whole-genome sequences can give rapid new insights into bacterial processes. These new systems are proposed to affect the *mafB* and *fhaB* genes, although these are still subject to experimental investigation for functional confirmation (Klee *et al*., 2000; Parkhill *et al*., 2000).

Another source of flexibility is achieved through the variable expression of the many phase-variable genes in these species (Saunders *et al*., 2000; Snyder *et al*., 2001). Phase variation is typically associated with genes involved in environmental change (Salaün *et al*., 2003; Saunders, 2003), and the preponderance of these genes in these species are associated with mediating direct interactions with the host, and immune evasion. The analysis of the complete genome sequences led to the prediction of the complete repertoires of phase variable genes in these species, which are amongst the largest so far seen in any species, providing the capacity to generate vast numbers of combinations of expressed and unexpressed genes. An additional insight gained from using a comparative genome analyses methodology for the identification of these genes was that not only are the genes' phase variably expressed but also the presence of the genes frequently differs between strains, as does their potential to phase-vary. So, while two strains may possess the same gene, this gene's expression can be mediated by phase variation in one but not the other, and in a third strain the gene may be missing entirely. A very similar pattern is seen in *H. pylori*, in which species this has been explored in more detail (Salaün *et al*., 2004).

The short-motif simple sequence repeats mediating phase variation have been recognized for some time to generate diversity within the population through changes in length in this species. Comparisons of the genes containing longer repeats for which changes in length would be associated with changes in the composition of the genes containing them, rather than leading to ON–OFF switching, suggests that this is also important in generating diversity in this species. Comparison of the genomes was used to identify a number of genes containing coding tandem repeats, which were then pursued in a diverse strain collection to determine whether these were a source of diversity. In total, 22 such genes were identified within the *Neisseria* spp., of which 16 were demonstrated to display different numbers of repeats between different strains of the same species (Jordan *et al*., 2003). This is another example of the way in which genome analysis can be extended from "index" sequenced strains to the wider population.

Differences between the strains are not limited to coding sequences, although the functional consequences of other differences are usually far harder to interpret. Two intergenic sequences that appear to be unique to the *Neisseria* spp., although not restricted to the pathogenic species, are the neisserial uptake signal sequence (Goodman and Scocca, 1988; Elkins *et al*., 1991) and the Correia repeat and associated Correia Repeat Enclosed Elements (Correia *et al*., 1986; Correia *et al*., 1988; Liu *et al*., 2002). While a single complete neisserial genome allows the identification of the locations of these sorts of elements, the comparison of multiple genomes has allowed the differences in their locations and functions to be assessed as well (Liu *et al*., 2002; Snyder *et al*., 2003).

While genomes are now an essential context for the identification of new candidate genes for classical gene-by-gene investigations and for the design of constructs and experiments, they also provide the basis for whole-system studies of bacterial behavior and function. The strain MC58 genome sequencing project was unusual in that it represented a highly interactive three-way collaboration between a company (Chiron), an academic research group (in Oxford University), and a sequencing centre (TIGR). The results of this interaction were reflected not only in the publication of the genome sequence itself (Tettelin *et al*., 2000), but also of an extensive study of all of the predicted surface proteins as vaccine candidates (Pizza *et al*., 2000). This group, as well as several others, have developed microarray tools for the investigation of cellular functions and behavior under different infection-related conditions (Grifantini *et al*., 2002a,b; Dietrich *et al*., 2003; Grifantini *et al*., 2003; Kurz *et al*., 2003). Progressively, these tools are becoming routine components of the study of these pathogens, just as they are of others, and the essential platform that the genome sequences and high-quality annotations represent to these endeavors has to be considered for a proper appreciation of the impact of the genome sequences in this field. Similarly, as proteomic approaches to these pathogens develop, this too will depend upon the genome sequences and their annotations.

Short Specialist Review

Kinetoplastid genomics

Chris Peacock and Christiane Hertz-Fowler
The Wellcome Trust Sanger Institute, Cambridge, UK

The Kinetoplastida are a group of flagellated protozoa characterized by the kinetoplast, a specialized extranuclear DNA contained within the single mitochondrion. As an order, they are very versatile at adapting to their environment, existing both as free-living organisms through to obligate parasites of plants, insects, fish, reptiles, birds, mammals, and humans. Kinetoplastida are divided morphologically into two distinct suborders. The Bodonidae contain parasitic, ectocommensal, and free-living species, while the members of the Trypanosomatidae suborder are all obligate parasites. Research focuses predominately on members of the Trypanosomatidae, in particular, the human and veterinary pathogens within the genera *Leishmania* and *Trypanosoma* and the "model" Kinetoplastida within the genera *Crithidia* and *Leptomonas*. The diverse pathology caused by these parasites causes morbidity and mortality to millions of people and domestic livestock each year, with hundreds of millions at risk in approximately 90 countries (WHO reports).

The Kinetoplastida are one of the earliest diverging eukaryotic organisms (Sogin *et al*., 1986), encoding genes of bacterial and possible plant origin within their genomes (Hannaert *et al*., 2003b; Couvreur *et al*., 2002; Krepinsky *et al*., 2001; Sinha *et al*., 1999). They exhibit many classical eukaryotic pathways, yet have adapted the means to flourish in their differing host environments, using some processes that are either unique to the Kinetoplastida or that were initially elucidated in this group and subsequently discovered in other eukaryotes (e.g., RNA editing, trans-splicing of mRNAs, glycosylphosphatidylinositol anchoring of proteins (Ferguson, 1999), compartmentalization of energy metabolism (Hannaert *et al*., 2003a)). Although *Trypanosoma* and *Leishmania* spp share many aspects of "basic biology", they differ fundamentally in terms of their pathology and the hostile niches they inhabit within their hosts and vectors.

Three large-scale genome projects, initiated in the mid-1990s under the auspice of multicenter genome networks, have resulted in the near complete sequence and annotation of the 36 chromosomes of *Leishmania major* (reference strain MHOM/IL/80/Friedlin) genome, the 11-Mb chromosomes of *Trypanosoma brucei* (TREU927/4) and up to 20 chromosomal bands of *Trypanosoma cruzi* (CL Brener strain) by an international consortium (see Table 1 for further details). The genome projects have been underpinned by detailed karyotype analyses as well as genetic and physical maps (Tait *et al*., 2002; Melville *et al*., 2000; Ivens *et al*., 1998; Santos *et al*., 1997; Henriksson *et al*., 1995). They have also greatly benefited from

the large volume of other genomic data publicly available (Table 1). This varies from individually characterized genes submitted to the public databases, through to more extensive projects sequencing expressed sequence tags (ESTs), genome survey sequences (GSS), or cosmid and BAC clones (Aguero *et al*., 2000; Verdun *et al*., 1998; Levick *et al*., 1996; El-Sayed and Donelson, 1997; El-Sayed *et al*., 1995). More recently, whole genome shotgun projects of additional *Leishmania* and *Trypanosoma* species have been undertaken (Table 1).

Initial studies have shown significant physical differences between the genome architecture of the three major pathogenic groups sequenced so far. Whereas *L. major* exhibits little chromosome length polymorphisms between the homologs of each of the diploid chromosomes (Ivens *et al*., 1998), *T. brucei* (Melville *et al*., 2000) and *T. cruzi* (Porcile *et al*., 2003) show extensive homolog variations. As a consequence of such polymorphisms, haploid genome contents have been challenging to assemble, particularly in *T. cruzi*. Such genome plasticity is thought to be a result of not only the existence of mobile genetic elements in both *T. brucei* and *T. cruzi* but also of the expansion of both gene families, such as the retrotransposon hot spot proteins in the subtelomeric regions of chromosomes, and the presence of repetitive sequences (Bringaud *et al*., 2004; Hall *et al*., 2003; Wickstead *et al*., 2003; Bhattacharya *et al*., 2002; Bringaud *et al*., 2002a; Bringaud *et al*., 2002b). In the case of *T. brucei*, it has recently emerged that RNA interference, a mechanism apparently absent in both *L. major* and *T. cruzi*, is involved in the regulation of retroposon transcript abundance and thus of genome integrity (Ullu *et al*., 2004; Shi *et al*., 2004).

Even prior to their completion, the individual sequencing projects have not only reaffirmed previous experimental observations on a larger scale but revealed insights into interesting kinetoplastid biology. The data published from the three genomes so far (McDonagh *et al*., 2000; Worthey *et al*., 2003; Hall *et al*., 2003; El-Sayed *et al*., 2003; Andersson *et al*., 1998; Ghedin *et al*., 2004) and, in the case of *L. major*, confirmed by nuclear run-on analyses (Monnerat *et al*., 2004; Martinez-Calvillo *et al*., 2003; Martinez-Calvillo *et al*., 2004) are concurrent with our understanding of transcription and translation in these organisms. Genes are arranged in highly compact blocks on the same strand with small intergenic regions separating one gene from the next. Transcription takes place in long polycistronic units with gene regulation being predominantly controlled posttranscriptionally (reviewed by Campbell *et al*., 2003; Clayton, 2002). However, there is little evidence of genes being clustered on the basis of either related function or similar expression levels (Hall *et al*., 2003; El-Sayed *et al*., 2003).

Trans-splicing of a highly conserved 39 nucleotide sequence – the spliced leader – onto the 5′ end of all mRNAs (Parsons *et al*., 1986; Kooter *et al*., 1984) occurs cotranscriptionally with the simultaneous polyadenylation of the upstream transcript (Sutton and Boothroyd, 1986; LeBowitz *et al*., 1993), generating monocistronic transcripts. The spliced leader sequence is encoded in a single array (Roberts *et al*., 1996), the true extent of which will be unraveled by the genome projects. Cis-splicing is rare, with a single instance of an intron in both *T. brucei* and *T. cruzi* having so far been published (Mair *et al*., 2000). Despite the biochemical characterization of the three classical RNA polymerases in Trypanosomatids, no sequences with RNA polymerase II promoter activity transcribing protein coding

genes have been either experimentally characterized or identified computationally – although there is some evidence that the strand switch region between two polycistronic regions appears to be essential at least in *L. major* (Dubessay *et al*., 2002).

Extensive research has also focused on the content and organization of the telomeric and subtelomeric regions, particularly in *T. cruzi* and *T. brucei*, where genes mediating host immune system evasion and modulation are encoded. *T. brucei* periodically switches expression of variant surface glycoproteins (VSGs), a process termed *antigenic variation* (recently reviewed by Barry *et al*., 2003; McCulloch, 2004). VSGs are encoded on all three classes of chromosomes and transcribed from telomeric expression sites located on megabase and intermediate sized chromosomes. Monoallelic expression of one VSG gene is ensured by recruitment of a single expression site into a subnuclear body (Navarro and Gull, 2001). It is now emerging that VSGs are present as silent arrays in chromosome-internal locations, apparently predominantly as pseudogenes (El-Sayed *et al*., 2003) and require recombination events to form functional VSG genes. The structure of up to six expression sites and the organization of a small proportion of VSG gene repertoire have been described (Berriman *et al*., 2002). However, the completed genome project and ensuing work will provide further insight into how VSG diversity is maintained and activated during antigenic variation.

T. cruzi, despite being an obligate intracellular parasite, also expresses families of surface antigens, some of which are encoded at the telomeres (Chiurillo *et al*., 1999).

In contrast, *Leishmania* utilizes the host's complement pathway to gain entry to, and reside in, cells of the monocyte lineage, a process that requires stage specific differential expression of surface expressed genes (reviewed by Matlashewski, 2001).

In contrast to the nuclear genome, deciphering the mitochondrial DNA, consisting of a few dozen maxicircle and thousands of minicircle structures, has not been part of the genome projects. The sequences of these minicircles and maxicircles were determined in an effort to elucidate the mechanism of uridine insertion/deletion RNA editing of the mitochondrial mRNA transcripts, a process originally described in Trypanosomatidae (reviewed by Simpson *et al*., 2003; Estevez and Simpson, 1999).

The sequencing of the genomes of these organisms is only the start of a long process of using this wealth of data to complement what is already known about their complex biology, eventually aiding in the development of new ways to combat the effects of the pathogenic members of this group. It is very noticeable that almost all the frontline drugs used against these organisms have not only been in use for decades (leading to drug resistance) but also have detrimental toxic effects on the patients. There are as yet no commercial vaccines for any of these parasites and vector and reservoir control programs are at best maintaining the status quo. Comparative genomics will help to identify genes and regulatory sequences that are unique to Kinetoplastida and unique to individual species. Selecting species for sequencing that differ in specific aspects of pathogenicity, host tropism, or survival strategy allows candidate genes to be identified that may encode those specific differences. These genes may provide leads for further functional experimentation. Already the striking conservation of gene function and order is becoming apparent within this group, as are the regions of divergence (Ghedin *et al*., 2004; Bringaud *et al*., 1998).

Large-scale functional genomics projects are essential for turning sequence and annotation into information with practical implications. Data are already publicly available from large-scale 2D gel proteomic (Drummelsmith *et al*., 2003) and RNAi (TrypanoFAN, **http://trypanofan.path.cam.ac.uk/cgi-bin/WebObjects/trypanofan**) projects, complemented by emerging information from array technologies investigating host/pathogen interaction (Mukherjee *et al*., 2003) as well as expression patterns of the pathogen alone (Akopyants *et al*., 2004; Almeida *et al*., 2004; Saxena *et al*., 2003; Diehl *et al*., 2002; Minning *et al*., 2003). Ultimately, the availability of so much genomic data in the public domain should hasten the identification of new candidates for drug targets, vaccines, and diagnostic tools.

Short Specialist Review

The organelles of apicomplexan parasites

James W. Ajioka and Elizabeth T. Brooke-Powell
University of Cambridge, Cambridge, UK

Kiew-Lian Wan
Universiti Kebangsaan Malaysia, Bangi, Selangor DE, Malaysia

1. Introduction

All eukaryotic cells are chimeric insofar as two major organelles, the mitochondrion and chloroplast, are products of primary endosymbiotic events with an alpha-proteobacterium and cyanobacterium respectively. The evolutionary history of the apicomplexa represents a further degree of complexity as a result of a secondary endosymbiotic event between a eukaryotic cell and a photosynthetic algae (Fast *et al*., 2001; Foth and McFadden, 2003). The mitochondrial and apicoplast genomes are very small, 6 kb linear and 35 kb circular respectively, compared to their counterparts in other species, each encoding a minimum of proteins (Feagin, 1992; Roos *et al*., 2002). The reduced nature of these genomes may be accounted for by both loss of genes and transfer of genes to the nuclear genome (*see* Article 54, **The nuclear genome of apicomplexan parasites**, Volume 4; Huang *et al*., 2004; Foth and McFadden, 2003).

2. The mitochondrial genome

With the exception of *Cryptosporidium* spp. (Abrahamsen *et al*., 2004), apicomplexans carry a single mitochondrion that maintains a membrane potential and retains some electron transport proteins (Srivastava *et al*., 1997; Vercesi *et al*., 1998). Evidence varies between species as to its ability to produce ATP via oxidative phosphorylation (see, for example, Srivastava *et al*., 1997; Vercesi *et al*., 1998). Alternatively, the organelle's main function may be to remove electrons generated by dihyrdroorotate dehydrogenase in the de novo synthesis of pyrimidines (Gero *et al*., 1984; Prapunwattana *et al*., 1988). Although only the mitochondrial genomes of *Plasmodium* species have been well characterized, DNA sequence

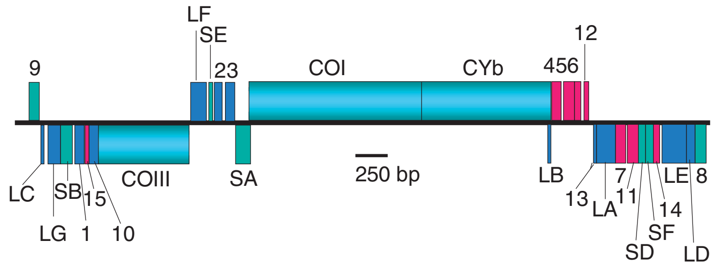

Figure 1 Single unit of the tandemly repeated *P. falciparum* mitochondrial genome map. Green boxes correspond to small subunit rRNA fragments, whereas blue boxes correspond to large subunit rRNA. The red boxes correspond to transcripts with characteristics like the rRNA fragments, which cannot be specifically placed in small or large subunit rRNA (known as misc RNA in Table 1). Details of the mapping coordinates can be found in Table 1 (Reproduced with the kind permission of J. E. Feagin)

data suggest that it is conserved through the apicomplexa (Vaidya *et al*., 1989; Feagin, 1992; McFadden *et al*., 2000; Feagin, 1994); see Figure 1 and Table 1). The 6-kb mitochondrial genome is arranged as a linear concatemer of about 20 unit copies per cell, replicates via a rolling circle mechanism, and appears to be uniparentally inherited from the macrogametocyte (Preiser *et al*., 1996; Creasey *et al*., 1993). It is one of the smallest known mitochondrial genomes, encoding only three proteins in the electron transport chain and small fragmented rRNA genes (Feagin, 1992; Ji *et al*., 1996; Feagin *et al*., 1997). The rRNAs range in size between 40 and 200 nt, and the genes are interspersed between the genes encoding the cytochrome *c* oxidase subunits I and III (COI and COIII) and the apocytochrome *b* (CYb). The isolation and characterization of apocytochrome *b* in both *Plasmodium falciparum* and *Toxoplasma gondii* demonstrate that these genes encode functional proteins (Vaidya *et al*., 1993; Srivastava *et al*., 1999; McFadden and Boothroyd, 1999). The detection of nearly whole-genome sized transcripts suggest that the genome is polycistronically transcribed, but the standing RNA pools contain mostly processed single transcripts (Ji *et al*., 1996). Transcript mapping studies revealed that the genes do not overlap but are very closely packed to the extent that some of the rRNA genes do not have any intervening sequence between them (Feagin *et al*., 1997; Rehkopf *et al*., 2000). Moreover, the polyadenylation of the processed transcripts results in very short or absent tails where the pattern is gene specific. From these findings, it is speculated that the control of RNA abundance is through precise cleavage of the polycistronic RNA and stability of the processed transcripts. The functional constraints imposed by this system may limit possible variations such that apicomplexan mitochondrial genomes evolve more slowly than their counterparts in other organisms.

3. The apicoplast genome

An elegant synthesis of molecular evidence with previous microscopic observations led to the rediscovery of an organelle now known as the apicoplast (for recent

reviews, see Archibald and Keeling, 2002; Foth and McFadden, 2003). Amongst the morphological descriptions of a variety of apicomplexans were reports of a multimembranous organelle, variously called the "Hohlzylinder" and "Golgi-adjunct" (Siddall, 1992), but despite repeated observations, the organelle's function remained a mystery. Electron microscopic studies of *Plasmodium lophura* showed a circular DNA thought to be mitochondrial (Kilejian, 1975). This observation was confirmed by the analysis of density-gradient fractionated whole genomic

P. knowlesi DNA that revealed a band that represented an A-T-rich circular 35-kb DNA (Williamson *et al*., 1985). Subsequent reports on studies of *P. falciparum* suggested that this 35-kb circular DNA was of plastid origin and might be associated with a nonmitochondrial organelle (see Figure 2 and Table 2). Observations including the inverted repeat structure of the genes encoding the large and small subunit ribosomal RNAs (rRNAs) and split RNA polymerase *rpoC1* and *rpoC2* genes provided strong evidence that the 35-kb circular DNA is a degenerate plastid genome (Gardner *et al*., 1991a,b; Gardner *et al*., 1993). The localization of small subunit rRNA transcripts with an antisense probe to *T. gondii* thin sections provided the first direct evidence that the multimembranous organelle is a four-membrane-bound degenerate plastid (Kohler *et al*., 1997). The organelle's four-membrane composition suggests that the apicoplast is derived from a secondary endosymbiotic event with a photosynthetic eukaryote and may pre-date the origin of the phylum, and hence be a shared characteristic with all alveolates (Williams and Keeling, 2003). Although there is an ongoing debate as to whether the apicoplast is of green or red algal origin, the balance of arguments favor a rhodophyte (red) alga (Williams and Keeling, 2003).

The 35-kb apicoplast genomes characterized in *Plasmodium* spp., *T. gondii*, and *Eimeria tenella* are nearly identical structurally and, despite the differences in nuclear genome G+C contents, they are all very A+T rich; *P. falciparum* (86%), *T. gondii* (78.5%), *E. tenella* (79.4%) (see Figure 2 and Table 2; Cai *et al*., 2003). The apicoplast genomes have some of the major characteristics of chloroplast genomes but appear to encode only a fraction of the genes observed in the chloroplast (Foth and McFadden, 2003). For example, the *T. gondii* apicoplast genome maintains 33 tRNAs capable of translating all codons and 28 predicted coding sequences (CDS) encoding 17 ribosomal proteins, *tuf*A, *clp, rpo*B, *rpo*C1, *rpo*C2, ORF470 (*ycf* 24), and five CDSs of unknown function (see Figure 2 and Table 2). This limited coding capacity suggested that the vast majority of the organelle's proteins are encoded in the nucleus. Plastids carry out many other functions aside from photosynthesis, and plastid-related fatty acid, isoprenoid, and heme biosynthesis appear to be retained in the apicoplast. The Type II fatty acid synthesis protein, acyl carrier protein (ACP) showed putative orthologs in both *P. falciparum* and *T. gondii* databases and the *T. gondii* version was demonstrably targeted to the apicoplast (Waller *et al*., 1998). Importantly, this study showed that ACP and other apicoplast-targeted proteins shared a long N-terminal extension that functions as a bipartite signal required for the secretion and entry into the organelle. Synthesis of isoprenoids such as sterols and ubiquinones require isopentenyl diphosphate as a precursor, and apicomplexans depend on the mevalonate-independent 1-deoxy-D-xylulose 5-phosphate (DOXP) pathway for this function. The *P. falciparum* DOXP synthase and DOXP reductoisomerase orthologs can be functionally inhibited and target the apicoplast via a bipartite N-terminal extension (Jomaa *et al*., 1999). A systematic search of the *P. falciparum* genome for this signature bipartite signal sequence estimates that 500–600 proteins target to the apicoplast (Gardner *et al*., 2002).

Note: The *Plasmodium falciparum* coordinates do not correlate with the *Toxoplasma gondii* coordinates because the Pf GenBank accession numbers are split.

Compared to photosynthetic plastids, the apicoplast function is very limited, with current evidence restricted to Type II fatty acid and isoprenoid biosynthesis. Although the 35-kb genome encodes transcriptional and translational machinery, the vast majority of proteins associated with apicoplast function are encoded in the nucleus and imported via a bipartite signal sequence.

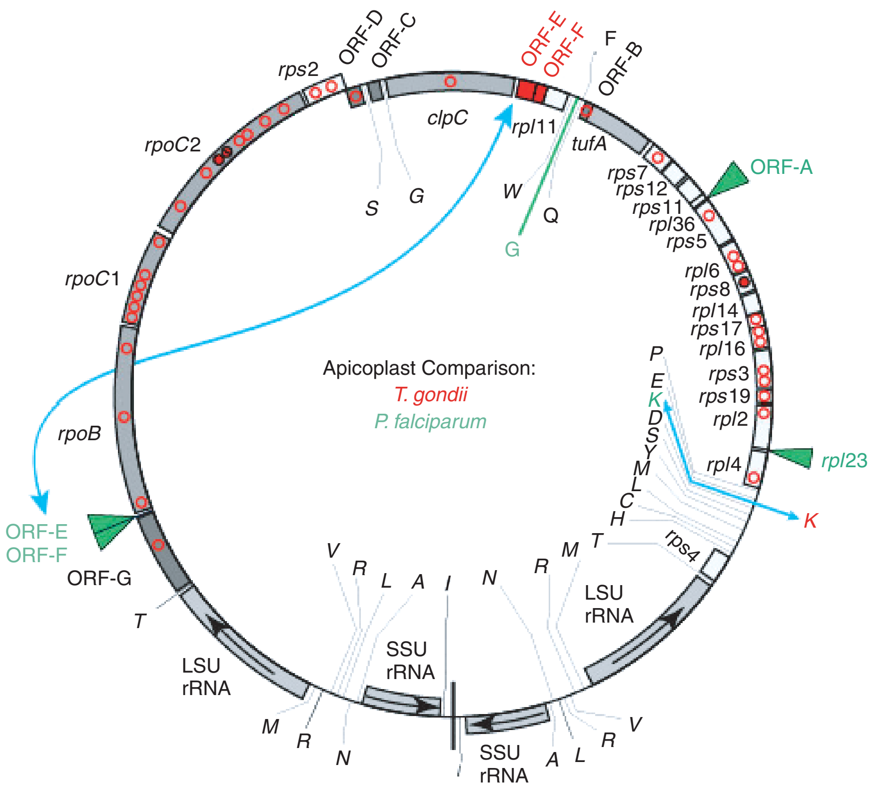

Figure 2 Combined map of *T. gondii* and *P. falciparum* apicoplast genome. The *E. tenella* apicoplast sequence has been completed and is identical to the *T. gondii* map shown (GenBank Reference AY217738). Red text indicates features that are present only in the *T. gondii* and *E. tenella*, whereas green text indicates *P. falciparum* specific features. Red open circles indicate the presence of in-frame UGA codons predicted to encode tryptophan, and filled red circles represent the presence of an in-frame stop codon (UAA and UAG; represented as misc_feature in Table 2). Short Specialist Review

Environmental shotgun sequencing

Gene W. Tyson
University of California, Berkeley, CA, USA

Philip Hugenholtz
Department of Energy Joint Genome Institute, Walnut Creek, CA, USA

1. Introduction

Genome sequencing has revolutionized the study of microorganisms. Determining the complete genetic makeup of an organism, in principle, lays bare its metabolic potential and evolutionary history. However, microbial genomes sequenced to date lack environmental context. They are derived from microorganisms maintained in pure culture on artificial growth media and are unlikely to be representative of the population or community from which they were obtained. This limitation can be bypassed by direct sequencing of microbial communities from the environment. Two decades ago, Norman Pace and colleagues outlined an approach to use ribosomal RNAs (rRNAs) as phylogenetic markers for the organisms present in an environmental sample by extracting DNA, PCR-amplifying, cloning, and sequencing rRNA genes directly from the sample (Pace *et al*., 1986). This approach revealed and continues to reveal an extraordinary diversity of organisms in the microbial world, orders of magnitude greater than had been appreciated by culture-dependent techniques (Head *et al*., 1998; Hugenholtz, 2002). While markers such as 16S rRNA give an indication of which organisms are present in the environment, it reveals little about what those organisms might be doing. The natural progression of the rRNA-based work, therefore, was the direct cloning and sequencing of genomic DNA from environmental samples into large insert vectors such as BACs and fosmids (Beja *et al*., 2000a; Rondon *et al*., 2000). These genomic libraries are typically screened for rRNA genes (and other conserved markers) and clones are fully sequenced. Because of the size of the genomic inserts, dozens of protein-coding sequences associated with the rRNA gene can be identified. Using this approach, Ed DeLong and colleagues discovered genes for light-driven proton pumps (proteorhodopsins) in ocean waters belonging to an uncultivated lineage of marine *Gammaproteobacteria*, strongly suggesting a major role for phototrophy in marine ecosystems (Beja *et al*., 2000b; Beja *et al*., 2001). This strategy, however, reveals only a fraction of the metabolic potential of a community. Therefore,

when shotgun sequencing was demonstrated as a viable approach to quickly obtain complete organism genome sequences (Fleischmann *et al*., 1995; *see also* Article 2, **Genome sequencing of microbial species**, Volume 3), it was only a matter of time before it was applied to microbial communities. The first communities to be studied using an environmental shotgun sequencing approach were an acid mine drainage (AMD) biofilm (Tyson *et al*., 2004) and samples of the Sargasso Sea (Venter *et al*., 2004). The AMD biofilm is a low-diversity community nominally comprising three bacterial and three archaeal members by 16S rRNA analysis, and the Sargasso Sea samples are moderately complex comprising several hundred 16S rRNA phylotypes. Large genomic fragments of the dominant community members could be reconstructed by assembly of shotgun sequence reads in both studies, verifying the feasibility of the approach.

2. The impact of environmental shotgun sequencing on microbial ecology

Direct sampling of microbial communities provides insight into the metabolism of uncultured organisms and an overview of community function. For example, the bacterial members of the AMD biofilm were inferred to be the primary producers of fixed carbon and nitrogen in the community, and the archaeal members appear to be adapted to scavenge these nutrients mainly in the form of amino acids (Tyson *et al*., 2004). In the Sargasso Sea study, a large number of proteorhodopsin homologs were identified, suggesting that phototrophy is a widespread strategy for energy production in the ocean (Venter *et al*., 2004).

Environmental sequence data can also provide clues for the cultivation of uncultured microorganisms. For instance, only one set of nitrogen fixing genes was identified in the AMD genome data belonging to an uncultured bacterial member of the community. This provided the basis for a directed isolation strategy using nitrogen-free media, which resulted in a pure culture of the targeted bacterium (Tyson *et al*., in prep).

One long recognized drawback of PCR-based molecular surveys is the reliance of the method on broad-specificity primers to amplify the gene of interest from all organisms in an environmental sample. Therefore, microorganisms with mismatches to these primers may be overlooked. Shotgun sequencing bypasses this problem as it does not rely on PCR. A striking example of this was the unexpected identification of a novel euryarchaeota in the AMD biofilm, which was missed during an exhaustive analysis of a 16S rDNA PCR clone library because it has three mismatches to one of the conserved primers (Baker *et al*., in prep).

One of the most exciting aspects of environmental shotgun sequencing is the ability to resolve population structure of cohabiting and coevolving strains and species. This is possible because each shotgun read likely originates from a different individual within a population, giving an overview of the genomic variation within that population. To date, population genetics has largely relied on comparison of isolates, usually pathogens, from different habitats (Spratt *et al*., 2001). One intriguing observation from the AMD data is that for one archaeal species population at least,

individual genomes are recombinant mosaics of closely related strains (Tyson *et al*., 2004). This suggests that, contrary to current opinion, genetic exchange akin to that in sexual organisms may be the cohesive force holding microbial species together. Since the frequency of homologous recombination decreases exponentially with genome divergence (Vulic *et al*., 1997), some microbial species may be naturally defined by their ability to recombine. However, genomic mosaicism is an isolated observation in an extreme habitat that needs to be confirmed with other sympatric microbial populations.

3. Hurdles and caveats

Environmental shotgun sequencing presents a number of technical challenges, both experimental and computational. Central to the success of any sequencing project is the extraction of high-quality DNA. Since environmental samples contain multiple species, a second objective is to obtain DNA from all community members quantitatively representative of each species in the sample. Microbial ecologists conducting 16S rRNA-based molecular surveys have recognized this for many years and devoted much attention to optimizing DNA extraction procedures for a range of habitats. The extraction step is even more critical for direct cloning of environmental DNA since PCR is not available as a buffer to provide high-quality DNA. For example, DNA extracted from AMD samples suitable for PCR amplification has proven difficult to clone into large insert vectors (unpublished observations). Shotgun libraries (~3-kb inserts) may be the only viable approach for some environmental samples where obtaining high-purity DNA suitable for direct cloning results in low-molecular-weight DNA.

Assembly of environmental shotgun sequence data presents a number of challenges. In contrast to sequencing a microbial isolate where all reads are derived from a single clonal genome, environmental sequences sample the genomes of multiple strains and species. Standard assembly methods can easily reconstitute the genomes of different species from a mixed pool of sequence reads but genetically distinct strains are often assembled into single composite genomic fragments (Tyson *et al*., 2004; Venter *et al*., 2004). This has the benefit of highlighting single nucleotide polymorphisms within a population but is problematic when trying to apply standard population genetics methods in which strain separation is essential (Hartl, 1997). It may be possible to resolve fragments of individual strain genomes by increasing assembly stringency and sequencing coverage; however, novel methods will likely need to be developed to analyze composite genomic fragments. In highly complex environments, such as soil, assembly may not be feasible (Figure 1) without a vast amount of sequencing, which is currently impractical given the cost of DNA sequencing (Tringe *et al*., in prep). Therefore, it will be important to develop methods that can utilize single reads for comparative analysis.

Environmental shotgun sequencing introduces a new element to genome data analysis. Since a microbial community comprises multiple species, the genomic fragments obtained from the community need to be binned or classified into their respective populations. This was achieved using a combination of GC content, read depth, and similarity to isolate genomes for both the AMD and Sargasso Sea

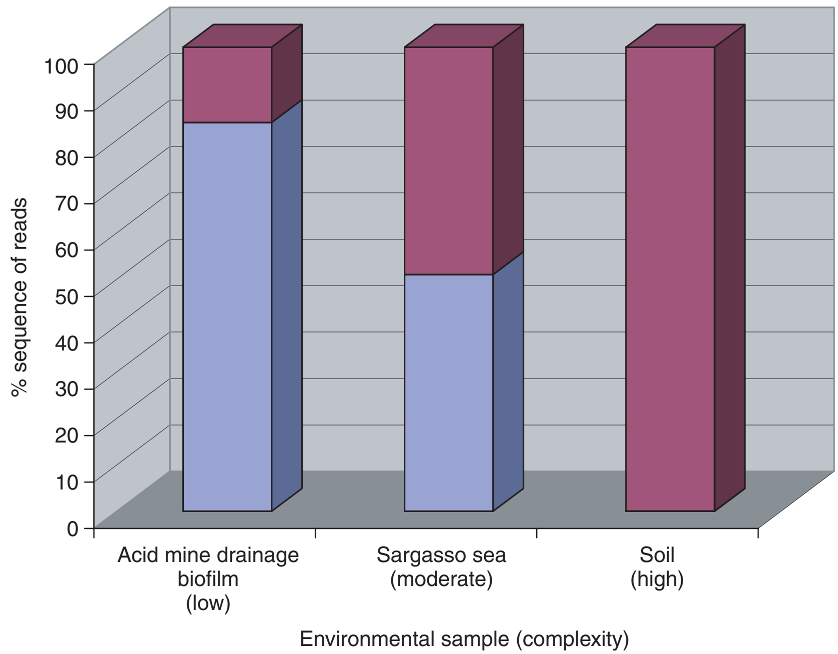

Figure 1 Effect of community complexity on the ability to assemble environmental shotgun sequence data. As community complexity increases from low (acid mine drainage biofilm; Tyson *et al*., 2004) to moderate (Sargasso Sea; Venter *et al*., 2004) to high (soil; Tringe *et al*., in prep.), the ability to assemble the data decreases. All datasets were normalized for amount of sequence. Blue: assembled reads; Red: unassembled reads

studies. Each of these criteria have limitations; for example, different species may have indistinguishable GC contents, read depth varies within a given genome, and the accuracy of similarity-based binning is dependent on having sequenced genomes of closely related phylogenetic neighbors. Our current sampling of the tree of life is highly skewed owing to a cultivation bias (Hugenholtz, 2002), meaning that many lineages are poorly sampled for representative genomes. Isolates obtained from the environmental sample under study provide the best reference points for binning since they are representatives of populations in the community. For example, an isolate of one of the archaeal populations in the AMD biofilm was invaluable for separating two AMD populations indistinguishable by GC content and read depth (Tyson *et al*., 2004). Genome signatures, such as oligonucleotide frequencies, hold promise for finer scale binning of environmental genome fragments because they are distinctive even for closely related organisms (Teeling *et al*., 2004).

Ecologists have shown that many natural communities follow a lognormal species abundance distribution characterized by a few dominant and many rare species (Magurran and Henderson, 2003). This distribution was observed in the environmental genomic data at both the species and the strain level (Tyson *et al*., 2004) and resulted in sampling of only the numerically dominant populations with little or no sampling of rare populations. This caveat of the method is easily overlooked in the deluge of sequence data, and can have important implications

for assembly, binning, and annotation of the data since sampling unevenness can deleteriously affect all three. Methods that could be used or adapted to access rare populations in a community include normalized libraries (Patanjali *et al*., 1991) or physical isolation of cells prior to DNA extraction and library preparation (Zengler *et al*., 2002).

An emerging issue with environmental sequence data is data handling. For example, the Sargasso Sea study generated 1.045 Gb of nonredundant genome sequence that temporarily swamped the NCBI database until it and the AMD data were placed in a separate environmental sequence database. Furthermore, basic genome analyses such as all versus all comparisons scale quadratically and pose a real computational challenge for large environmental sequence datasets.

4. The promise of environmental shotgun sequencing for microbial ecology and evolution

Environmental shotgun data enabled by emerging technologies such as microarrays and proteomics hold great promise for the field of microbial ecology. In the next decade, these technological advancements should place organisms in the context of their community and environment, reveal how communities function as a whole, provide one or more definitions of a microbial species, explain how differentiation arises within a sympatric population, and reveal the importance of natural selection in the evolution of microbial species.

Short Specialist Review

Methods for detecting horizontal transfer of genes

Jeffrey G. Lawrence
University of Pittsburgh, Pittsburgh, PA, USA

1. Introduction

Bacteria and Archaea are well known to reproduce by binary fission, whereby the genetic material contained in the parental cell is typically replicated and passed to daughter cells unfettered except for the action of mutational processes. Yet, it has long been recognized that superimposed upon this fundamental biology lies the process of gene exchange, whereby cells can receive genetic material from a nonmaternal parent (Koonin *et al*., 2001; Ochman *et al*., 2000). Despite careful exploration of the mechanisms of gene exchange since the early twentieth century, well-documented cases of gene exchange among both closely and distantly related organisms, the identification – by independent methods – of numerous genes recently introduced into bacterial genomes by gene transfer, and dramatic phenotypic differences among closely related strains that can be directly attributed to gene change (Lawrence and Ochman, 2002), the role of this process in the evolution of microbial genomes remains a contentious, hotly debated issue (Gogarten *et al*., 2002; Kurland, 2000). While no one doubts that gene transfer occurs, valid questions remain as to what the overall impact of the process has been.

Herein, I will discriminate between two classes of gene transfer, both of which may be properly labeled as "horizontal" or "lateral." First, genes may be mobilized among genomes of closely related strains, typically via conjugation, transformation, or bacteriophage-mediated transduction. After introduction into the cytoplasm, the introduced DNA is recombined into a stable replicon by enzymes that perform homologous recombination. This process results in allelic change, or gene replacement. Its effects were initially measured by isozyme analysis, then multilocus enzyme electrophoresis, DNA sequence analysis, and now large-scale MultiLocas Sequence Typing (MLST) approaches. In all cases, the loss of linkage disequilibrium between distinct loci of different genes is taken as a measure for the rate of DNA exchange by this route. The phenomenon of intragroup gene exchange lies beyond the scope of this review. Instead, I will focus on methods for detecting DNA exchange among distantly related organisms; such transfer events usually do not rely upon homologous recombination to introduce the incoming DNA into a stable replicon, and gene acquisition – which can alter dramatically the

physiological capabilities of the recipient organism – often results (Lawrence, 1999, 2002). It is this sort of process, for example, that can lead to the rapid adaptation of certain strains of *Escherichia coli* as pathogenic organisms (Welch *et al*., 2002).

At the center of assessing the impact of gene transfer comes the identification of foreign genes themselves. Numerous methods have been employed, and cogent reviews of their methodology appear elsewhere. Herein, I review the two major classes of methods employed to identify genes introduced into the genome from a foreign source, with an emphasis on how and why different methods detect different sets of genes in the same genome. That is, it is critical to recognize two features of any approach for the identification of alien genes: (1) what one finds depends strongly on the method employed and typically reflects a fundamentally different null hypothesis being tested (Lawrence and Hendrickson, 2003) and (2) any method can provide at best a probability that a gene has been introduced into the chromosome from a foreign source; no method can provide a straightforward yes-or-no answer as to whether a gene is "native" or "foreign." Considering that the number of genes shared among free-living bacteria has been estimated at <200, and among all prokaryotes at <80, it is highly likely that no gene has not experienced horizontal transfer at some point during its tenure within a lineage (Ragan and Charlebois, 2002). While genes may be transferred with different efficiencies (Jain *et al*., 1999), no gene appears immune to HGT (horizontal gene transfer). Genes encoding core metabolic functions, conserved biosynthetic pathways, components of the transcription and translation apparatus, and even ribosomal RNA have been subject to HGT (Gogarten *et al*., 2002). Robust identification of the genes most likely to be subject to transfer, the phylogenetic scope of their potential recipients with respect to their donor, and other issues lie at the heart of placing HGT within the context of the multitude of factors influencing microbial evolution (Lawrence and Hendrickson, 2003).

2. Phylogenetic methods

HGT can occur between phylogenetically distantly related organisms, for example, between bacteria and Eukarya (Garcia-Vallve *et al*., 2000). As a result, phylogenetic inferences derived from different molecules from the same set of taxa are only rarely completely congruent; when they are, the genes are typically found in all taxa represented in the data set (Daubin *et al*., 2003); among genes found only in a subset of taxa, phylogenetic congruence is rarely observed (Clarke *et al*., 2002; Ragan and Charlebois, 2002). Therefore, the effects of HGT in confounding phylogenetic reconstruction have been taken as evidence for its existence, although alternative explanations cannot be excluded (Doolittle, 1999a,b; Koonin *et al*., 2001; Nelson *et al*., 1999). Phylogenetic methods rely upon gene relationship to infer gene transfer, although formal creation of phylogenetic trees is often not performed. Methods often attempt to discern atypical distributions of genes across genomes, and may include the identification of (1) genes present in isolated taxa but absent from closely related species (implying gene gain), (2) genes with an unusually high degree of similarity to genes found in otherwise unrelated taxa (Clarke *et al*., 2002), and (3) genes whose phylogenetic relationships are not

congruent with the relationships inferred from other genes in their respective genomes (Doolittle, 1999a,b, 2000; Olendzenski *et al*., 2000).

Caveats to all phylogenetic approaches include the confounding effects of convergent evolutionary forces, the amplification of gene families that prevent the robust identification of orthologues, and phylogenetic artifacts such as long-branch attraction (Philippe and Forterre, 1999). As a result, even apparent robust conclusions for widespread gene transfer based on phylogenetic methods (Raymond *et al*., 2002) may be called into question based on questions of methodology (Daubin *et al*., 2003; Daubin and Ochman, 2004).

3. Parametric measures

In contrast, phylogeny-independent methods identify genes that appear atypical in their current genomic context. Here, discordance is interpreted as reflecting long-term evolution in genomes with different mutational biases. Mutational biases result naturally during the DNA replication process as the mutational proclivities of DNA polymerases, the specific dNTP and tRNA contents of the cell, lineage-specific mismatch-repair systems, and other variables contribute to directional mutation pressures (Sueoka, 1988). Such parametric methods examine nucleotide and dinucleotide frequencies (Karlin and Burge, 1995; Lawrence and Ochman, 1997, 1998), codon usage biases (Karlin *et al*., 1998; Moszer *et al*., 1999), or patterns uncovered by Markov chain analyses (Hayes and Borodovsky, 1998) or minimum entropy analyses (Azad *et al*., 2002).

Early applications of parametric methods suffered from poor characterization of "typical" chromosomal genes, which prevented robust identification of "atypical" genes (Koski *et al*., 2001). More advanced methods employ more rigorous criteria for gene length (Lawrence and Ochman, 2002), increase the number of parameters being analyzed, and often employ iterative and floating baseline techniques to quantify "typical" genic parameters with a higher degree of accuracy (Lawrence, unpublished data). Moreover, new techniques will combine multiple analytical approaches, thereby preventing the foibles of any one method from leading the investigators to ambiguous or misleading conclusions (Hsiao *et al*., 2003).

4. No one answer

Each of the methods described above has been used to infer that substantial portions of different genomes have arisen by HGT. However, each method examines different properties of the genes or genomes; as a result, they naturally identify different subsets of genes as being "foreign." In each case, what kinds of genes obtain this label is a function of the method employed. For genes identified as atypical, only those recently acquired may be identified, since the process of gene amelioration will erase the mutation bias signal of the donor genome over time (Lawrence and Ochman, 1997, 1998). In contrast, phylogenetic methods may detect ancient transfer events (Woese *et al*., 2000) but cannot identify genes that were acquired from relatively closely related organisms. Therefore, the different methods

are appropriate for testing different sorts of hypotheses (Lawrence and Ochman, 2002; Ragan, 2001a,b).

Short Specialist Review

Genomics of *Rickettsia*

Hiroyuki Ogata
Structural & Genomic Information Laboratory, UPR 2589, IBSM, CNRS, Parc Scientifique de Luminy, 13288 Marseille Cedex 9, France

Didier Raoult
Unité des Rickettsies, UMR 6020, IFR 48, CNRS, Faculté de Médecine, 13385 Marseille Cedex 5, France

1. *Rickettsia*

Rickettsia are classified in the α subgroup of proteobacteria (Raoult and Roux, 1997). In nature, rickettsiae live in arthropods such as ticks, fleas, lice, or mites. In arthropods, most rickettsiae are vertically transmitted from mother to their progeny by transovarial transmission. Human beings are incidental hosts infected by arthropod bite or by autoinoculation through infected feces. Rickettsioses are mild to severe diseases presenting usually with fever, headaches, and a rash. In humans, rickettsiae multiply in vascular endothelial cells or in monocytes (e.g., *R. akari* and *Orientia tsutsugumushi*). Due to their obligate association with hosts, rickettsiae have few opportunities to exchange genes with other bacteria (*see* Article 66, **Methods for detecting horizontal transfer of genes**, Volume 4), although recent studies provide evidences for rather ancient gene exchanges with bacteria living in amoeba. Rickettsiae need to regulate their metabolism to synchronize their life cycle to that of the host. For example, rickettsiae are quiescent in ticks when the hosts are resting. When the tick temperature increases after feeding, the rickettsiae are reactivated and start to multiply. Metabolic activity of the hosts provides various nutrients accessible to rickettsiae, and makes many de novo biosynthetic pathways of rickettsiae nonessential for their life. This allowed the degradation of unnecessary genes and caused extensive genome reduction.

2. Genome organization

Genome sequences have been determined and published for five *Rickettsia* species: *R. prowazekii* (Andersson *et al*., 1998) and *R. typhi* (McLeod *et al*., 2004) of the typhus group (TG), *R. conorii* (Ogata *et al*., 2001) and *R. felis* (Ogata *et al*., 2005a) of the spotted fever group (SFG) and the earliest diverging species, *R. bellii* (Ogata *et al*., 2006). *Rickettsia* genomes are reduced in size and rich in adenine/thymine bases. Most of the sequenced genomes are comprised of a single

circular chromosome. However, they still exhibit substantial intraspecies variations in terms of size, gene composition; repeat content as well as the presence of extra chromosomal DNA elements. The size of the sequenced genomes varies between 1.1 and 1.5 Mb. The number of predicted protein-coding genes varies from 834 (for *R. prowazekii*) to 1512 (for *R. felis*). Repeated DNA sequences (*see* Article 9, **Repeatfinding**, Volume 7) are rare (0.3%) in the genomes of TG *Rickettsia*, while relatively abundant in the SFG *Rickettsia* (1.6–4.3%). In addition to the main chromosomal DNA, *R. felis* exhibits circular plasmids.

3. Genome content

Three axes characterize the strategies that *Rickettsia* adopted for their parasitic intracellular life: (1) the ability of invading the hosts, (2) the ability of up taking nutrients, and (3) the ability of synchronizing their replication with that of the host cells.

3.1. Host invasion

Through horizontal transmission involving a mammal–arthropod cycle, *Rickettsia* propagate in the host populations (Azad and Beard, 1998). *Rickettsia* enter nonphagocytic cells such as intestinal epithelial cells by inducing the formation of a phagocytic vacuole, and rapidly escape from the membrane-bound vacuole into the host cytoplasm (Gouin *et al*., 2005). Genome analysis allowed the identification of five genes with potential membrane-lytic activities: a hemolysin (*tlyA*, *tlyC*), a phospholipase D (*pld*), and a patatin-like phospholipase A (*pat1*, *pat2*). Recent experimental data suggests that *tlyC* and *pld* have a role in the process of escape from the phagocytic vacuoles (Whitworth *et al*., 2005). After being internalized in the cytoplasm, *Rickettsia* start replication. SFG *Rickettsia*, *R. bellii* as well as *R. typhi* induce actin polymerization at their surface and move around intra- and intercellularly (Gouin *et al*., 2005). The genome sequencing of *R. conorii* revealed a candidate gene responsible for this actin-based motility (Ogata *et al*., 2001). The product of the gene, named as *RickA*, was later demonstrated to have a critical role in the induction of actin polymerization (Jeng *et al*., 2004; Gouin *et al*., 2004). Two outer membrane proteins, rOmpA and rOmpB, have been suggested to have a role in adhesion to host cells (Li and Walker, 1998; Uchiyama, 2003). These two proteins are members of a large paralogous gene family, the “surface cell antigens (Sca)”. The analysis of the *Rickettsia* genomes revealed 17 members of the Sca family (Blanc *et al*., 2005). Interestingly, the genes for the Sca proteins exhibit remarkably diverse patterns of presence/absence across different species. The *N*-terminal parts of these proteins, which are exported to the cell surface, are highly variable between orthologs. It is suggested that accelerated amino acid changes and differential gene degradation of Sca paralogs contributed to the intraspecies variation of those cell-surface proteins and adaptation to different environments. All *Rickettsia* genomes contain genes encoding proteins with ankyrin repeats and tetratricopeptide repeats. *R. felis* and *R. bellii* genomes are especially enriched with

those genes. These repeats are protein–protein interaction motifs found in diverse organisms, and involved in different cellular activities including cell division. Their roles in the adaptation of parasites to their hosts have been suggested (Mosavi *et al.*, 2002; Rubtsov and Lopina, 2000; Blatch and Lassle, 1999). Rickettsiae may alter the intracellular environment of their hosts for survival, by targeting those proteins to the hosts. Finally, *R. felis* possesses additional genes potentially involved in the host invasion process such as a hyaluronidase gene, a chitinase gene, and a gene for a homolog of ecotin.

3.2. Uptake of nutrients

Rickettsia genomes lack genes for the glycolytic pathway and exhibit a restricted set of genes for the biosynthesis of small molecules such as amino acids, nucleotides, and cofactors. To compensate for the lack of genes for the biosynthesis of small molecules, *Rickettsia* exploit the host cells by different transporters. All *Rickettsia* exhibit five paralogs for the ATP/ADP translocases, hallmark enzymes for the energy parasitism of rickettsiae and chlamydiae. All *Rickettsia* possess a gene for the transporter of *S*-adenosylmethionine (SAM) (Tucker *et al.*, 2003), which is an essential methyl donor in various methyltransferase reactions. This contrasts with the degradation of the SAM synthetase gene (*metK*) in most *Rickettsia* species (Andersson and Andersson, 1999; Driskell *et al.*, 2005). *Rickettsia* genomes encode a number of paralogs for the ATP-binding cassette transporters and for the major facilitator superfamily transporters (*see* Article 81, **Transporter protein families**, Volume 6). Some of those transporters are predicted to be specific to amino acids and nucleotides. However, the substrate specificities of these transporters are mostly unknown.

3.3. Synchronization of replication

Most *Rickettsia* species are stably associated with their arthropod hosts for a long period of time. *Rickettsia* are thus thought to have developed a regulatory mechanism to synchronize their replication with that of the hosts. Genome analyses suggest that *spoT* and toxin–antitoxin (TA) systems could be the major players in this process (Ogata *et al.*, 2005a). Despite their reduced genome size, all the sequenced *Rickettsia* possess paralogous *spoT* genes. SpoT and RelA control the concentration of alarmone, (p)ppGpp (guanosine tetra- and pentaphosphates) in response to starvation in enterobacteria (Chatterji and Ojha, 2001). The alarmone in turn acts as an effector of transcription and changes the global cellular metabolism (i.e., "stringent response"). *Rickettsia* genomes contain many fragmented *spoT* paralogs (4–14 copies), some of which contain ppGpp hydrolase domain and others, which contain the ppGpp synthetase domain. In *R. felis*, all the 14 *spoT* genes were demonstrated to be transcribed (Ogata *et al.*, 2005a). In *R. conorii*, the transcription of five *spoT* genes are regulated depending on the stress or the type of infected hosts (Rovery *et al.*, 2005). The chromosomes of SFG *Rickettsia* and *R. bellii* harbor genes for TA systems (Ogata *et al.*, 2005a, 2006). Genes for TA systems were originally identified in bacterial plasmids. TA systems are

composed of toxin and antitoxin gene pairs, and ensure stable plasmid inheritance by a mechanism known as *postsegregational killing* when they are encoded in plasmids. Recent genome surveys showed that TA systems are also abundant in the chromosomes of bacteria (Gerdes *et al*., 2005). It is suggested that TA systems encoded in the bacterial chromosomes participate in the cascade of the stringent response pathway. Thus, the rickettsial TA systems might contribute to the global regulation of metabolism, eventually leading to selective killing (a primitive form of bacterial apoptosis) or reversible stasis of bacterial subpopulations during period of starvation or other stress (Gerdes, 2000; Engelberg-Kulka and Glaser, 1999). Alternatively, the rickettsial TA systems could be targeted to the host cells, and help the bacteria to persist in the host.

4. Plasmids and conjugation

Genome sequencing of *R. felis* were identified, besides a circular chromosome, two circular plasmids of 39 and 63 kb, respectively (Ogata *et al*., 2005a). The larger plasmid exhibits a cluster of several genes for conjugative DNA transfer. Conjugative plasmids have a role in the exchange of genes with other bacteria. Indeed, the *R. felis* genome bears traces of ancient gene acquisitions from nonrickettsial bacteria, along with gene transfers back-and-forth between the chromosome and the plasmids. The sequencing of the earliest diverging *R. bellii* later revealed a more complete gene cluster for conjugative DNA transfer (Ogata *et al*., 2006). By electron microscopy, sex pili-like surface appendages physically connecting rickettsial cells (i.e., mating pairs) were observed for both *R. felis* and *R. bellii*. The lack of genetic transformation tools for rickettsiae has hindered progress in the molecular characterization of the bacteria. The rickettsial plasmids and the conjugal DNA transfer genes are expected to provide a molecular basis for the development of a genetic transformation tool to study rickettsiae.

5. Genome evolution

Besides the massive amplification of transposase genes in the genomes of *R. bellii* and *R. felis*, few cases of recent lateral gene acquisition and gene duplication have been identified in *Rickettsia*. This is consistent with their protected and restricted intracellular niches. Hence, the majority of the variations between different *Rickettsia* genomes originate in the genome reduction that has degraded different sets of genes across different *Rickettsia* lineages. Except *R. bellii*, the genomes of *Rickettsia* exhibit remarkably similar overall gene orders. The long-range genome colinearity allowed precise identifications of orthologous loci between the genomes, and helped detailed analyses of gene degradation process. Comparison of the *R. prowazekii* and *R. conorii* genomes allowed the recognition of many gene remnants in the noncoding regions of the genomes, and suggested that most of the genome differences between the two genomes were derived by genome degradation (Ogata *et al*., 2001). Furthermore, the comparison led to the identification of various intermediate stages of gene deterioration process, including

fragmented genes and "split genes". The detection of mRNAs from those split genes suggests that some, if not all, of them may still retain their functions.

All *Rickettsia* genomes harbor palindromic sequences of about 100–150 bp, known as *Rickettsia palindromic elements* (RPEs) (Ogata *et al*., 2000, 2002). Remarkably, several families of RPEs exhibit a capability of inserting themselves within protein-coding genes and generating new peptide segments (30–50 aa) in the gene products. Recent analyses showed similar phenomena in *Wolbachia* (Ogata *et al*., 2005b) and *Methanocaldococcus jannaschii* (Suyama *et al*., 2005). It is hypothesized that such insertions of palindromic elements into genes might have contributed to the divergence of protein sequences in the course of bacterial evolution (Claverie and Ogata, 2003).

Despite the lack of evidence for recent gene transfers, *Rickettsia* genomes exhibit traces of ancient gene acquisitions especially from bacteria living in amoeba (Ogata *et al*., 2006). Phylogenetic analyses suggest that some of the genes associated with intracellular parasitism have been acquired from bacteria living in amoeba. For example, several authors suggest that the ancestral gene for the ATP/ADP translocase was transferred from *Parachlamydia* to *Rickettsia* (Greub and Raoult, 2003; Schmitz-Esser *et al*., 2004). The conjugal DNA transfer genes are most similar to those found in *Parachlamydia*. Furthermore, comparative sequence analyses revealed the abundance of rickettsial genes exhibiting a high level of sequence similarity to the homologs in amoeba-associated bacteria, including *Legionellaceae*, *Burkholderiaceae*, *Pseudomonadaceae*, *Parachlamydiaceae,* and *Coxiella*. The ancestor of *Rickettsia* might have lived within amoeba, given the capability of *R. bellii* to survive within amoeba and the finding of amebal symbonts related to *Rickettsia* (Fritsche *et al*., 1999). Since many amoeba-associated bacteria or their relatives are pathogens of humans, amoebae have been suggested to act as evolutionary "training grounds" for bacteria to prepare the ability to infect the cells of higher eukaryotes (Molmeret *et al*., 2005; Barker and Brown, 1994). Gene exchanges between these bacteria may have significantly contributed to their evolution, by conferring an immediate selective advantage in the adaptation to the intracellular environment of eukaryotic cells.

6. Conclusion

Genomics of *Rickettsia* has revealed remarkable diversities of their genomes, as recently illustrated by the discovery of the putative conjugative plasmid in *R. felis*. Further determinations of new *Rickettsia* genome sequences will provide more comprehensive pictures of the molecular and evolutionary diversity of these medically important intracellular bacteria.

Short Specialist Review

Listeriae

Carmen Buchrieser and Philippe Glaser
Unité de Génomique des Microorganismes Pathogènes and CNRS URA 2171
Institut Pasteur, 75724 Paris Cedex 15, France

1. Introduction

Listeriae are gram-positive rods of low G + C content, which are present in a variety of animals and niches, including processed food. *Listeriae* are resistant to extreme conditions, such as high salt concentrations (10% NaCl), a broad pH range (from 4.5 to 9.0), and a wide temperature range (4–45°C), demonstrating a great adaptability to different environments. The genus *Listeria* contains six species, two of which are pathogenic: *Listeria monocytogenes*, the food-borne human pathogen responsible for listeriosis, on which this chapter is focused, and *Listeria ivanovii*, an animal pathogen (Vazquez-Boland *et al*., 2001).

L. monocytogenes is the causative agent of listeriosis, a systemic bacterial infection that causes miscarriage in pregnant women and that is often fatal to immunocompromised individuals (Farber and Peterkin, 1991; Jurado *et al*., 1993). In addition, *L. monocytogenes* is a leading cause of meningitis in neonates and the elderly. The mortality rates can be as high as 30%, and the fetal death rate caused by *Listeria* is most likely higher due to an unknown number of unexplained abortions attributable to *Listeria*. Recently *L. monocytogenes* was also shown to cause gastroenteritis (Aureli *et al*., 2000; Dalton *et al*., 1997; Riedo *et al*., 1994).

The ability of *Listeria* to grow at low temperatures and under high salt conditions allows its spread by contaminated food, such as soft cheese and meat products, even when they have been properly stored. Several large outbreaks of listeriosis have been traced back to food production and packaging plants, demonstrating that this organism is well suited to exploit weaknesses of the food distribution system.

Listeria disseminates from the intestinal lumen to the central nervous system and the feto-placental unit. In the infected host, *Listeria* survives to host defenses owing mainly to its resistance to phagocyte killing and to its capacity to invade nonphagocytic cells where it can replicate. The cell biology of the infectious process has been investigated in detail and *L. monocytogenes* has become a paradigm to study intracellular parasitism (Cossart and Lecuit, 1998).

Despite the elucidation of several players necessary for entry and intracellular replication of *L. monocytogenes* (Vazquez-Boland *et al*., 2001) many open

questions remain, like “How does *L. monocytogenes* cross the blood-brain barrier?” or “What is the genetic basis of virulence differences among different *L. monocytogenes* strains?” or “What are the specific features allowing *Listeria* to grow at low temperatures and thus to replicate in refrigerated food?”

With the aim to answer these questions a comparative genomics approach was applied by a consortium of 10 European laboratories, by sequencing the genome of the pathogen *L. monocytogenes* (strain EGDe) and the closely related nonpathogenic species *Listeria innocua* (strain CLIP11626) (Glaser *et al*., 2001) (**http://genolist.pasteur.fr/ListiList/**). This comparison revealed that all known virulence factors are absent from the apathogenic, closely related *L. innocua* and pointed to new putative virulence genes, which were analyzed functionally during the last years. Additional *Listeria* genome sequences were obtained three years later by TIGR in collaboration with the FDA (Nelson *et al*., 2004), which now allow the comparison of several different isolates from the same species. At present there are three complete and two partial, published *Listeria* sequences available (Table 1). *Listeriae* contain one circular chromosome of about 2.9 Mb and an average G + C content of 39%. Two of the sequenced strains (*L. monocytogenes* H7858 and *L. innocua*) contain a plasmid of about 80 kb in size that resemble each other and the plasmid pOX2 identified in *Bacillus anthracis* (Read *et al*., 2002).

Table 1 General features of published *Listeria* genome sequences

	L. monocytogenes EGDe (1/2a)	*L. monocytogenes* F6854 (1/2a)[c]	*L. monocytogenes* F2365 (4b)	*L. monocytogenes* H7858 (4b)[c]	*L. innocua* CLIP11262 (6a)

2. Genome organization and comparative genomics

The *Listeria* genomes have a conserved, colinear genome organization with around 60–100 regions of one to several Kbs, specific for each species, scattered around the chromosome and one to five (*L. innocua*) prophage regions. *L. innocua* and all *L. monocytogenes* except the serotype 4b strain (F2365) contain a phage of the A118 family (Glaser *et al*., 2001; Loessner *et al*., 2000) inserted in the *comK* gene. Furthermore each sequenced strain carries a monocin region. However, phages do not seem to play a role in virulence acquisition in *Listeria* as they are not carrying known or putative virulence genes and are not conserved among strains.

In spite of this mosaic structure, the three completely sequenced *Listeria* genomes show a very strong conservation in genome organization with no inversions or shifts of large genome segments (Figure 1) (Buchrieser *et al*., 2003). This conserved genome organization may be related to the low occurrence of

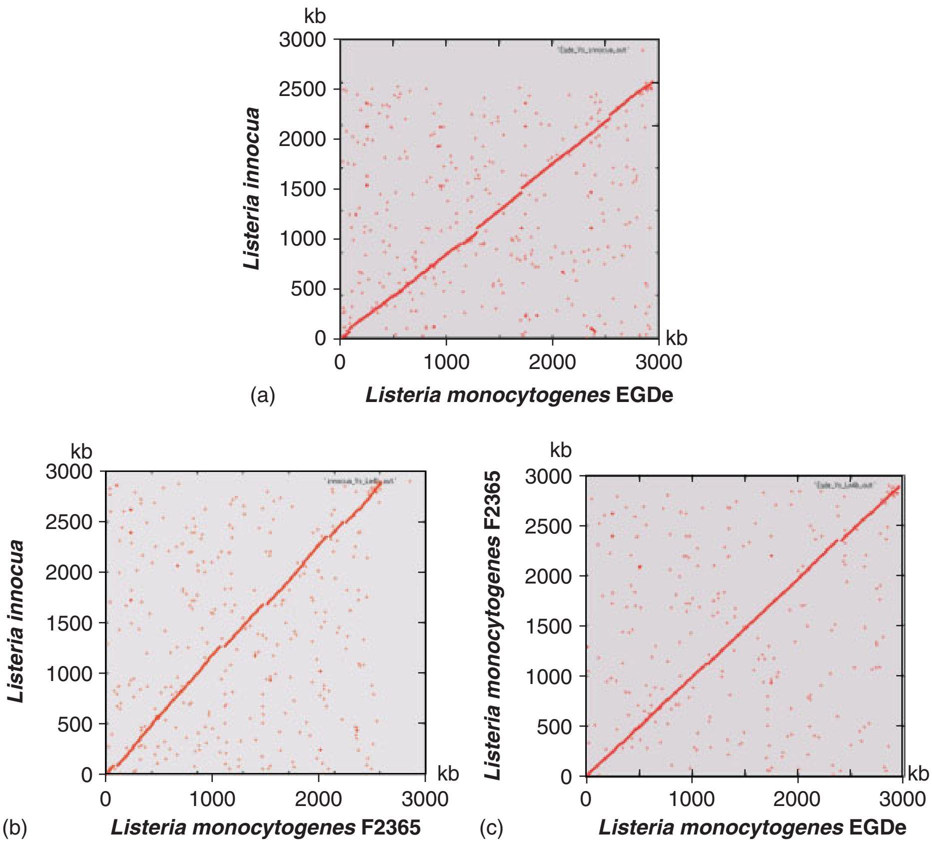

Figure 1 Synteny between (a) *Listeria monocytogenes* EGDe and *Listeria innocua* CLIP11262, (b) *L. innocua* CLIP11262 and *L. monocytogenes* F2365, (c) *L. monocytogenes* F2365 and *L. monocytogenes* EGDe. Orthologous genes were defined by bidirectional best hits based on Blastp comparisons

insertion sequences (IS) elements, suggesting that IS transposition or IS mediated deletions are not key evolutionary mechanisms in *Listeria*. The chromosome of the serotype 4b strains (F2365 and H7858) lack intact IS but do contain four transposases of the IS3 family that are present in homologous locations in both strains. The serotype 1/2a strains (F6854 and EGDe) each contain three while *L. innocua* contains four of these elements. Furthermore, the serotype 1/2a strains contain an intact IS element named ISLmo1, two are present in strain F6854 and three, one of which is not intact, are present in EGDe. ISLmo1 is missing in the serotype 4b and the *L. innocua* strains. The *Listeria* genomes contain putative DNA uptake genes, homologous to *Bacillus subtilis* competence genes. Thus competence may play a role in the evolution of *Listeria*.

3. Specific features of the *Listeria* genomes

The most striking features of the *Listeria* genomes are an exceptionally large number of surface proteins, an abundance of transport proteins, in particular, proteins, dedicated to carbohydrate transport, and an extensive regulatory repertoire. These are characteristics that are undoubtedly conferring on *Listeria* their adaptability to many diverse environments, like soil, water, effluents, a large variety of foods, and eukaryotic cells.

1. *Surface proteins*: Surface proteins have important roles in the interactions of microorganisms with their environments, in particular, during host infection. The *Listeria* genomes encode many such proteins, for example, 4.7% of all predicted genes of *L. monocytogenes* EGDe. The largest surface protein family are lipoproteins and the second largest family are LPXTG proteins including the internalin family. Major virulence factors of *L. monocytogenes* belong to the Internalin family, like Internalin (InlA) and InlB necessary to enter eukaryotic cells. Although the major known virulence factors are conserved, there is a pronounced diversity within the surface proteins of the different strains. For example, when comparing *L. monocytogenes* EGDe (serovar 1/2a) to *L. monocytogenes* F2635 (serotype 4b) five lipoproteins, nine LPXTG proteins and two autolysins are specific to the serotype 4b strain. As another example, among the 41 LPXTG proteins identified in *L. monocytogenes* EGDe, 11 are absent from *L. innocua* CLIP11262. *L. innocua* CLIP11262 codes for 34 LPXTG proteins, 14 of which are absent from *L. monocytogenes* EGDe (Cabanes *et al*., 2002; Glaser *et al*., 2001). This pronounced diversity among LPXTG proteins was further substantiated by a comparative genomics study using DNA/DNA array hybridization. The distribution of 55 genes coding for putative surface proteins belonging to two sequenced *L. monocytogenes* genomes (serotype 1/2a and 4b) and *L. innocua* CLIP11262 was investigated among 93 *L. monocytogenes* and 20 *Listeria* sp. strains. The analysis identified 25 surface protein-coding genes as specific for the species *L. monocytogenes* including *inlAB*. Others are specific for certain subgroups of strains or for *L. innocua* (Doumith *et al*., 2004). The fact that different subgroups

of *L. monocytogenes* strains contain different sets of surface proteins may reflect their different potential to cause disease or to multiply in different niches.

2. *Transporters*: The *Listeria* genomes encode an abundance of transport proteins (e.g., 11.6% of all predicted genes of *L. monocytogenes* EGDe). These comprise, in particular, proteins dedicated to carbohydrate transport conferring on *Listeria* probably in part its ability to colonize a broad range of ecosystems. The overall array of sugar transporters is similar in all *Listeria* genomes, in particular, among the four sequenced *L. monocytogenes* strains, but also in *L. innocua*. *Listeria* are predicted to transport and metabolize many simple as well as complex sugars including fructose, rhamnose, rhamnulose, glucose, mannose, chitin, sucrose, cellulose, pullan, trehalose, and tagatose. These sugars are largely associated with the environments where *Listeriae* are found. As in most bacterial genomes the predominant class corresponds to ABC transporters. Interestingly, most of the carbohydrate transport proteins belong to phosphoenolpyruvate-dependent phosphotransferase system (PTS) mediated carbohydrate transport genes. The PTS allows the use of different carbon sources and in many bacteria studied so far, the PTS is a crucial link between metabolism and regulation of catabolic operons (Barabote and Saier, 2005; Kotrba *et al*., 2001). The *Listeria* genomes contain an unusually large number of PTS loci (e.g., nearly twice as many as *Escherichia coli* and nearly three times as many as *B. subtilis*). Most of these PTS systems are conserved in the different sequenced genomes, however, subtle differences can be observed, probably allowing niche specific adaptation. An example is the family of β-glucoside-specific PTSs, of which eight are present in *L. monocytogenes* serotype 1/2a; two of those are missing in the *L. monocytogenes* serotype 4b strains and five are missing from *L. innocua*. As one of these β-glucoside-specific PTS systems, named *BvrABC*, was shown to be implicated in virulence of *L. monocytogenes* (Brehm *et al*., 1996) these differences might play a role in virulence differences among strains.
3. *Regulators*: Given the fact that *L. monocytogenes* is a ubiquitous, opportunistic pathogen that needs a variety of combinatorial pathways to adapt its metabolism to a given niche, an extensive regulatory repertoire is needed. Indeed, a little more than 7% of the *Listeria* genes predicted in the genomes are dedicated to regulatory proteins. Listeria have almost twice as many regulators than *Staphylococcus aureus* despite the similar genome size. Only *Pseudomonas aeruginosa* (Stover *et al*., 2000) another ubiquitous, opportunistic pathogen encodes more, with over 8% of its predicted genes being regulatory proteins. Diversity among the *Listeria* genomes with respect to regulatory genes is not as pronounced as the differences identified in the surface protein repertoire, suggesting they function primarily in specific niches common to the lifestyle of *Listeriae* outside a mammalian host. The most studied regulatory gene of *L. monocytogenes* is *prfA*, encoding the master regulator of virulence. In line with its function in regulating the expression of genes encoding proteins necessary for the entry and for intracellular multiplication of *L. monocytogenes*, PrfA is absent form *L. innocua* but conserved in all *L. monocytogenes* strains.

4. Concluding remarks and future directions

Sequencing the genomes of four *L. monocytogenes* strains and one *L. innocua* strain has brought a wealth of new data and insight into this fascinating pathogen. Now different genomics approaches are applied and provide for the first time a global view and a more and more complete knowledge on gene distribution and the genetic content present in the gene pool of the genus *Listeria*. This information represents a fundamental basis for functional studies to better understand phenotypic and virulence differences between *L. monocytogenes* strains and to gain knowledge on the evolution of the pathogen. The ongoing sequencing projects aimed at determining the complete genome sequence of one representative of each species of the genus *Listeria* (*L. ivanovii*, *L. seeligeri*, *L. welshimeri* and *L. grayi* strains) by the Institut Pasteur and the German PathoGenomiK network (**http://www.pasteur.fr/recherche/unites/gmp/**; **http://www.genomik.uni-wuerzburg.de/seq.htm**) and the determination of the complete genome sequence of an additional 19 *Listeria* strains by the Broad Institute (**http://www.broad.mit.edu/seq/msc/**) will be the driving force for understanding the function of the many factors encoded by the genome, whether involved or not in virulence, and to understand strain specific differences in niche adaptation and virulence.

Introductory Review

History of genetic mapping

Newton E. Morton
University of Southampton, Southampton, UK

1. Genetic and physical maps

Examples of linkage were reported in the first decade of the last century, but it was not until 1913 that Sturtevant elaborated the concept of linear arrangement in a *linkage map.* Recognition of double crossing-over and interference led to the understanding that linear arrangement implies not merely order of loci but the additivity of their distances. In 1919, Haldane introduced the Morgan (=100 centimorgans) as the length of a chromatid that on the average has experienced one crossover event per meiosis. This concept is the basis of genetic maps that have been adopted for all organisms. Over nearly a century, geneticists have become familiar with genetic distances and chromosome lengths in centimorgans (cM), and have reached substantial consensus about methods and results. On the contrary, a second type of *genetic map* with the essential properties of linearity and additivity is a recent invention still in rapid evolution (Maniatis *et al*., 2002). A *linkage disequilibrium map* determines the distance between pairs of loci not from recombination but from allelic association, also called linkage disequilibrium (LD), which is measured in linkage disequilibrium units (LDU). One LDU corresponds to the length of a chromatid in which on the average one crossover event has taken place in t generations, and so the resolution is t times as great as for the linkage map. This greatly increases the power to localize a gene within a candidate region at the expense of typing a larger number of markers and using methods that at this early stage are less transparent to many geneticists.

These two genetic maps (linkage and LD) do not exhaust the set of useful maps that are linear with additive distances. *Physical maps* (q.v.) depend not on crossing-over but on distance in the DNA sequence, ideally measured in base pairs (bp) or kilobases (kb). The closest approach to this ideal is by the DNA sequence nominally finished in 2003, although many relatively small errors remain, and of course, polymorphisms affecting the DNA sequence are omitted. The utility of *radiation hybrid maps*, based not on homologous crossing-over but on chromosome breakage, is limited to organisms without a finished DNA sequence. Finally, *chromosome bands* provide mutually exclusive and jointly exhaustive projections of genetic or cytogenetic candidate regions on the physical map as the first step in identification of genes that affect a phenotype of interest but are of unknown sequence and function. Their position must be refined on the genetic map before functional and physical studies become feasible.

2. Linkage mapping

The theory and practice of genetic mapping were established in experimental organisms before Bernstein (1931) realized that linkage could be detected in human pedigrees without knowing haplotypes. Geneticists who understood the importance of this insight made various modifications of his method, culminating in the elegant maximum likelihood u scores of Fisher (1935) and Finney (1940). Although fully efficient in the limit for loose linkage, only the asymptotic theory is known and it can be misleading in small samples. The scores are difficult to calculate except in simple two-generation pedigrees, and do not accommodate matings of known phase. They are inefficient for close linkage and do not estimate the recombination fraction accurately. It was not recognized that the low prior probability for linkage of two random loci implies an unusually stringent significant level to support a convincing claim of linkage.

In the early fifties, u scores were replaced by logarithms of odds (lods) based on the likelihood ratio of Neyman and Pearson (1928), as developed by Barnard (1949). The first application to human linkage was made by Haldane and Smith (1947) and extended by Smith (1953). Lods are simple, efficient, exact even in small samples, relatively easy to compute in large pedigrees, additive over samples, and provide a maximum likelihood estimate of recombination. It was inevitable that lods would replace u scores, but the question was whether they would take the Bayesian direction advocated by Barnard and Smith, which requires choice of a prior distribution and sacrifices additivity of scores. Wald (1947) provided a simpler approach that was applied to human linkage in the Ph.D. thesis of Morton (1955), who had experienced the limitations of u scores while analyzing pedigrees in Japan. A probability distribution for recombination was deduced that determined an appropriate significance level, an approach now used to control the false discovery rate (FDR) for both genome scans and functional tests (Storey and Tibshirani, 2003). The first application of lods showed that dominant elliptocytosis is caused by different mutations in different pedigrees (Morton, 1956). This encouraged the construction of genetic maps based initially on blood groups and isozymes as markers to localize an exponentially increasing number of disease loci. Sex-specific recombination was recognized (Smith, 1954; Renwick, 1968) and the power of heterogeneity tests was increased (Smith, 1963). Algorithms to consider multiple markers simultaneously and to reduce computational time in complex pedigrees were introduced (reviewed in Thompson, 2001). Theory that had no practical consequences before the DNA revolution became valuable as the number of markers increased. For example, Smith (1953) derived likelihoods for individuals homozygous for a rare recessive allele causing disease. This *autozygosity mapping*, a variant of linkage mapping in which the allele is not merely homozygous but identical by descent (loosely called homozygosity mapping), was not exploited until rediscovered by Lander and Botstein (1987) and shown to be a powerful method to localize such genes. DNA typing revealed great heterogeneity in most diseases and became the driving force for continued development of genetic mapping and ultimately for the physical map of the human genome.

Until near the end of the last century, most genes localized by genetic mapping were of large effect with high penetrance, low gene frequency, and dominance or

recessivity that could be reliably inferred by segregation analysis. The few attempts to detect oligogenes that are more common and of lower penetrance used methods that had been developed when the number of polymorphic markers was small (Penrose, 1935; Haseman and Elston, 1972). The models are weakly parametric, with the multiple parameters for gene frequency, penetrance, and interaction summarized by a smaller number of variance components. Ascertainment is often complex, segregation analysis inconclusive, and claims of linkage unconfirmed. The candidate region typically covers many centimorgans and therefore many loci. The relatively small number of confirmed locus identifications is a tribute both to the tirelessness of investigators and their subsequent use of LD and functional tests to identify a causal gene within a coarse candidate region suggested by linkage.

3. Association mapping

Linkage mapping depends on inference of recombination between two haplotypes in a single generation, interpreting pedigrees by a linkage map. *Association mapping* depends on the pattern of LD in single haplotypes, interpreted by an LD map. Currently, both approaches take as their prime objective the identification of a gene by determining a candidate region in the genome in the absence of information about the structure or function of the gene product. Such a candidate region may be determined by linkage, LD, or cytogenetic observation of a chromosomal aberration in probands. At that point, linkage has too little resolution to localize a gene, leaving LD as the method of choice until the candidate region is reduced to a few loci distinguished by functional tests (especially for a candidate locus), which share with LD the problem of distinguishing between association and causation.

During most of the last century, LD was a theoretical problem unrelated to association mapping, which even the most creative geneticists had not imagined. Robbins (1918) developed an evolutionary theory for LD between pairs of neutral loci, later extended to estimation of haplotypes from diplotypes (Hill, 1974). Sved (1971) developed a neutral theory conditional on identity by descent for pairs of diallelic markers, following Malecot (1948). The long interval between Robbins and Hill was dominated by the belief that LD is maintained through selection operating on all polymorphisms, of which only a few were then known (Ford, 1940). On this assumption, no useful theory of polymorphism could be developed without imagining the effects of selection. This impasse was broken by the discovery of many molecular polymorphisms, for most of which the neutral theory of Kimura (1968) was appropriate. Chakravarti (1984) used restriction fragment length polymorphisms (RFLPs), the first fruit of the DNA revolution, to infer a hot spot of recombination from an LD cold spot in the beta hemoglobin locus. Kerem *et al*. (1989) used LD to localize *CFTR*, the gene for cystic fibrosis, which stimulated Terwilliger (1995) to introduce composite likelihood (the product of dependent probabilities) as a mapping tool. In the absence of a relevant evolutionary theory, he was able to locate the *CFTR* gene, although the most frequent causal marker (ΔF508) lay outside his support interval. Devlin and Risch (1995) recognized that ascertainment bias should be allowed for the case-control design that is appropriate to rare genes. Their δ method is not applicable to more common

genes, because it assumes that the marker allele frequency approaches zero and the enrichment probability approaches ∞. The time was ripe for a more general solution. Collins and Morton (1998) introduced the association metric ρ, initially applied to rare major genes. Later extensions showed that the 20 years it took to localize the hemochromatosis gene (*HFE*) was a consequence of an unrecognized LD hot spot complementary to the LD cold spot noted earlier by Chakravarti, but understanding of blocks and steps came later (*see* Article 73, **Creating LD maps of the genome**, Volume 4). Daly *et al*. (2001) showed that most haplotypes do not recombine at LD cold spots, where the number of inferred recombinants is highly variable. Consequently, there are no natural haplosets within which each haplotype is delimited by recombination at the same pair of steps. A reasonable conjecture is that an unknown proportion of steps represent recombination hot spots dependent on DNA sequence, while the remainder occur independently and at random. Distinguishing rigorously between the two modes of origin is impossible without other evidence, which Jeffreys *et al*. (2001) provided by meiotic recombination. The large steps in their study represent small intervals with high crossing-over. A beginning has been made in identifying sequences that predispose to recombination (Tapper *et al*., 2003).

As soon as the LD fine structure was recognized, it gave birth to maps in additive LDU constructed from the association metric ρ that provides a basis for association mapping, in which they play the same role as linkage maps but at much greater resolution (Maniatis *et al*., 2002). LD maps are most reliable at high density, vary among populations, and increase in length with gene frequency and the number of generations since the last population bottleneck (Lonjou *et al*., 2003). Whereas microsatellites are currently most used for linkage analysis because of their high heterozygosity, single nucleotide polymorphisms (SNPs) are more useful for association analysis because of their much greater number and ease of typing. For brevity, it is customary to pool duplications, deletions, and insertions with the much larger number of SNPs. An international effort called HapMap is being made to create an SNP database that will be useful for many purposes, including creation of LD maps and choice of markers for association mapping (Couzin, 2002). A topic so young that it is missing from every book on genetics, bioinformatics, genomics, and statistics is being pursued by hundreds of investigators who may disagree about the means but not the importance of association mapping.

4. The future of genetic mapping

Linkage has such a long history that it is difficult to see what lies ahead. Meiotic recombination of SNPs in small candidate regions promises to recognize recombinogenic sequences, but extension to a whole chromosome would at present be a technical tour de force. It would identify recombination hot spots and give a linkage map at much greater precision than current maps, but this would not increase their resolution for gene localization in the absence of meiotic expression. Combined segregation and linkage analysis with credible allowance for ascertainment bias is so far restricted to major loci and single markers (Shields *et al*., 1994), but extension to multiple markers is possible and would be more

useful than continued modification of weakly parametric models that subsume gene frequency and other genetic parameters in a variance component.

Association mapping is so young that it has many more directions to expand. Composite likelihood remains a serious burden, but coalescence models have not provided the power that Monte Carlo simulation gives to genome scans by linkage. Nevertheless, genome scans by allelic association have much greater resolution than linkage, albeit at the cost of massive automation beyond the reach of most academics. It is an open question how long conventional genome scanning with microsatellites can compete with SNPs, which already dominate association mapping once a candidate region is identified. At present two-dimensional color graphics representing haplotypes, of untested utility for association mapping, are in competition with the additive distances of maps. These graphics depend entirely on association between adjacent SNPs and are therefore more sensitive to sample size and SNP density than LD maps based on covariances with neighboring SNPs (Ke *et al*., 2004). Undoubtedly, the suboptimal algorithms to construct LD maps will be improved, but it is not clear how haplotype graphs can be significantly improved. HapMap, faced with the problem of providing SNP data of general utility, has not yet decided whether to present its data as maps. Meanwhile, map determinants are being studied. Unlike linkage maps that have not been shown to vary among populations, LD maps are sensitive to demographic factors and especially to time since the last major bottleneck. Most but not all of the information in a local map can be extracted by fitting the Malecot model to a cosmopolitan map obtained by pooling samples from a larger region, even globally. A local map at low resolution, such as might be constructed for a genome scan, has intervals (called "holes") where the length is indeterminate and is therefore less reliable than a cosmopolitan map. Conversely, a local map at higher resolution, such as would be used to identify causal SNPs within a candidate region, may be substantially more reliable than a cosmopolitan map.

Construction of LD maps and their use for association mapping of disease susceptibility have the excitement of linkage mapping nearly a century ago. In the last stage of association mapping, and perhaps earlier, it will be complemented by advances in functional analysis aimed at causal SNPs. The haplotypes that carry a causal SNP are confounding variables that provide no additional information for its recognition. Once a causal SNP is identified, the haplotypes that carry it are of even less interest. In the last stage of association mapping, LD is superseded by functional tests in which presumptive causal SNPs are discriminated with allowance for association. These expression tests are, by definition, directed not at haplotypes but at causal SNPs, posing exactly the same disjunction between association and causation. The time is approaching when linkage, LD, and expression will be inseparable in the history of genetic mapping.

Introductory Review

Normal DNA sequence variations in humans

Kenneth K. Kidd

Yale University, New Haven, CT, USA

1. Introduction

For the past century, researchers have been identifying normal genetic variation and studying that variation in diverse human populations. However, population geneticists had relatively few genetic markers to use to study normal populations globally – in many parts of the world the markers were either not useful (polymorphic) or had not been studied. A breakthrough in human population genetics occurred with the demonstration in 1966 by Harry Harris that many red cell enzymes and serum proteins showed electrophoretic variation and could be used for population genetic studies (Harris, 1966). Human populations from around the world have subsequently been studied for many of those normal polymorphisms, and a large compendium of the data collected over the ensuing quarter century has been published (Cavalli-Sforza *et al*., 1994).

Those markers are now generally considered collectively as the "classical" polymorphisms because, starting in 1978, a new surge in identification of polymorphisms, this time directly in the DNA, began with the discovery of a DNA sequence polymorphism near the beta-globin gene (Kan and Dozy, 1978). By 1980, it was obvious that enough DNA-based polymorphisms would be available to generate a linkage map of *Homo sapiens* (Botstein *et al*., 1980). It was also clear that the limitations in human population genetics that resulted from relatively few classical markers being highly variable in all parts of the world would be overcome by the large numbers of DNA markers. There has been a near exponential increase in the numbers of DNA polymorphisms since then such that now more than 10 million are cataloged in dbSNP (Sherry *et al*., 2001), of which over 5 million are validated by two or more independent discoveries (build 123). Other databases with subsets of the information in dbSNP and other types of information that researchers find useful also catalog DNA sequence variation: HGVBase (Fredman *et al*., 2002) and JSNP (Hirakawa *et al*., 2002). One database, ALFRED, the ALlele FREquency Database (Osier *et al*., 2002; Rajeevan *et al*., 2003), is specifically devoted to cataloging allele frequencies for DNA-based polymorphisms in defined populations. None of those sources of information catalogs all of the polymorphisms of any one type that are currently known and described somewhere in the scientific literature,

but any one of them will identify a very large number of polymorphisms. Now the challenge is to understand this variation: Grand Challenge I-3 formulated by the National Human Genome Research Institute is "Develop a detailed understanding of the heritable variation in the human genome" (Collins *et al*., 2003). Understanding that variation has many components. Here, we focus on the description of the types of DNA sequence variation and on the pattern of variation around the world.

2. Types of variation

Two groups of DNA sequence variants can be distinguished – those that are by their nature diallelic and those that tend to be multiallelic. Among the diallelic polymorphisms are single nucleotide polymorphisms (SNPs) and insertions/deletions (Indels). The multiallelic polymorphisms include micro- and minisatellites and haplotyped loci. Haplotyped systems consist of two or more polymorphisms within a small segment of DNA. In addition, sequence variants on mitochondrial DNA (mtDNA) (*see* Article 5, **Studies of human genetic history using mtDNA variation**, Volume 1) and the nonrecombining part of the Y chromosome (NRY) (*see* Article 4, **Studies of human genetic history using the Y chromosome**, Volume 1) have uniparental inheritance with no recombination, and so each is intrinsically a single haplotypable locus in inheritance and population genetics. This brief introduction will not deal with those loci, but focus on variation in the autosomal genome.

2.1. *Diallelic polymorphisms (SNPs and Indels)*

Single-nucleotide polymorphisms (SNPs), the occurrence of different nucleotides at a specific place in the genome, are the most common type of human DNA sequence variation, occurring on average 1 per 500 to1000 bp on a randomly selected chromosome. As noted later, this number varies somewhat depending on the population studied. Insertion/deletion polymorphisms (Indels), the occurrence of some more or fewer nucleotides at one position of the genome, are less common but do occur frequently. The inserted/deleted sequence can be a few nucleotides long (Weber *et al*., 2002) up to several hundred nucleotides long, as is the case with the transposable Alu elements (Carter *et al*., 2004). Some very large polymorphic duplications, hundreds of kilobasepairs long, have also been identified (Sebat *et al*., 2004; Iafrate *et al*., 2004). Because these polymorphisms are diallelic, they are less informative than microsatellites; however, SNPs are more common in the genome and more amenable to automation and DNA chip technology. Most of the RFLPs (restriction fragment length polymorphisms) defined between the late 1970s and the late 1990s were SNPs in a restriction site but some were Indels occurring between restriction sites. Both SNPs and Indels are generally mutationally more stable than microsatellites; they can be considered as one-off events in evolution. That is, they are caused by a single mutational event that occurred once in the history of a species. We do not expect to see recurrent mutations at the same site

except as extremely rare events. For the polymorphic Alu elements, we know that the ancestral state is absence and the insertion of the Alu is the derived state. For the other markers, we cannot tell from the human polymorphism which allele is ancestral and which is derived. However, we can determine the ancestral state in almost all of those cases simply by determining the genotype of our nearest relatives, the other great apes, following the logic in Iyengar *et al*. (1998) (see also Hacia *et al*., 1999). In most cases, humans share a single allele with the other apes and, by inference, this is the ancestral or original allele in humans and the other allele is the derived allele.

2.2. Multiallelic polymorphisms (STRPs and VNTRs)

Microsatellites consist of approximately 10–50 tandemly repeated copies of particular DNA sequence motifs ranging from 1 to 10 (most commonly 2–4) nucleotide base pairs. These repeat sequences, discovered in 1989 (Weber and May, 1989; Litt and Luty, 1989), occur frequently and randomly across the human genome. When the repeat number is polymorphic, microsatellites are also called *short tandem repeat polymorphisms* (*STRPs*). (Other acronyms have also been used, e.g., SSLP.) STRP loci usually have multiple alleles and can have high levels of variation, that is, high heterozygosity. They rapidly replaced RFLP markers in gene mapping (especially disease genes) studies owing to these features and to their ease of typing, including the small amount of template DNA required. Remember that heterozygosity can never exceed 50% for a diallelic marker, whereas STRPs can easily have heterozygosities >75%. Because of this high heterozygosity, STRPs are the markers on which the most detailed human linkage maps are based (Dib *et al*., 1996; Kong *et al*., 2002; Jorgenson *et al*., 2005). STRPs have also become the standard for forensics and paternity testing (Budowle *et al*., 2001). The larger minisatellite arrays (also referred to as VNTRs, variable number of tandem repeats) are also highly polymorphic and powerful markers in forensic and paternity studies (DNA fingerprinting) (Jeffreys *et al*., 1985; Armour *et al*., 1996). However, they are less common than STRPs and are not evenly distributed throughout the genome. Their larger sequence motifs make them less amenable to PCR technology and use in genomic screening analyses. STRPs and VNTRs, on the other hand, tend to be much more dynamic than the diallelic SNPs and Indels. The mutation rates are higher, there are more alleles, and it is usually impossible to determine which is the ancestral allele.

2.3. Haplotypes

Polymorphisms of any type can be combined into groups of two or more tightly clustered on the chromosome – *haplotypes*. If two or more polymorphisms exist in close proximity in the DNA (e.g., up to a few thousands of bases apart), recombination will be extremely infrequent and they can be studied jointly as a haplotype. A haplotype is the *haploid genotype* of the alleles at polymorphisms along a rather short stretch of the chromosome. When the recombination rate

between any two markers is low, the history of the mutational events and random genetic drift result in a nonrandom occurrence of the alleles on chromosomes in the populations. This nonrandomness is called *linkage disequilibrium* (*LD*). Because recombination is very infrequent in molecularly very short regions, each of the possible haplotypes can be considered for analytic purposes as a distinct allele exactly analogous to alleles at any other polymorphism (SNP, Indel, etc.). We can estimate haplotype frequencies, haplotype heterozygosity, and so on. In samples of unrelated individuals, haplotypes require statistical inference because the individual sites are generally typed separately and 2^{n-1} genotypes are possible for n heterozygous sites. Several algorithms are used to estimate the actual phase, that is, which alleles at the heterozygous sites are on the same chromosome (Excoffier and Slatkin, 1995; Stephens *et al*., 2001b; among others). Within families, Mendelian rules will usually (but not always) allow the specific haplotypes to be inferred. Molecular methods can also determine phase, but they are tedious and usually provide little extra information over statistical inference (Tishkoff *et al*., 2000).

3. Global patterns of variation

Over the past century, researchers have identified normal genetic variation in antigens and proteins and studied that variation in diverse human populations to determine the amounts and distributions of that variation. With the advent of DNA-based markers in the last quarter century, these studies have accelerated. That information is being used to develop an understanding of the demographic histories of the different populations and the species as a whole, among other studies. These data support an "Out of Africa" hypothesis for human dispersal around the world, and are beginning to refine our understanding of population structures and genetic relationships. The historical-demographic explanation of the pattern is supported by the pattern of heterozygosity for STRPs and haplotypes, and by the pattern of LD in addition to the similarities in allele frequencies among populations.

3.1. Variation in the amount of intrapopulation variation: global distribution of heterozygosity

Most SNPs and diallelic markers that have been studied in multiple populations were initially ascertained in a non-African, usually European, population. This ascertainment bias results in the heterozygosity usually being quite high in European populations. Then, in most other populations it can only be lower since the maximum is 0.5. In the future, this bias will be less because more recent large-scale searches for SNPs are using samples with a significant non-European ancestry, especially ancestry from Africa. The evidence that is accumulating argues that there are more SNPs in African populations. STRPs that have been studied in multiple populations were generally ascertained in European populations or selected for additional study because of high heterozygosity in European populations. However, since additional alleles could be found in other populations, the heterozygosity is not limited to the values seen in European populations. Indeed, in all of the studies

done, the average heterozygosity of STRPs is higher in African than in European populations. Heterozygosity is generally lower in East Asian populations and even lower in Native American populations (Calafell *et al*., 1998; Jorde *et al*., 2000; Bowcock *et al*., 1994).

Haplotypes also tend to have high heterozygosity in African populations even though the individual SNPs are subject to the European bias. LD usually limits the allelic combinations seen in Europe. The consistent pattern of less LD in Africa results in more combinations occurring and the individual haplotypes common in Europe are usually less common in Africa. As with any generalization, there are exceptions, but the rule is well supported (e.g., Gabriel *et al*., 2002; Kidd *et al*., 2004). Other than that generalization, different haplotypes show a variety of different global patterns.

3.2. Variation in the amount of interpopulation variation

Baseline information for comparing findings at different loci is accumulating to aid in the identification of loci subject, now or in the past, to selection (directional or balancing). One standard measure of gene frequency variation among populations is the statistic F_{st} (Wright, 1969). This statistic can be related theoretically to random genetic drift as a function of time and effective population size, but can more simply be considered as a measure of the relative amounts of variation among populations shown by different genetic polymorphisms. The distribution of the F_{st} statistic for 369 individual SNPs studied in 38 populations representing all major continental regions shows a skewed distribution with Mean = 0.138 and a range of 0.042 to 0.380 (Kidd *et al*., 2004). Each population is represented by its own sample of individuals, averaging about 50 individuals, that is the basis for allele frequency calculations for all of the SNPs. None of the SNPs has any known or likely functional relevance. Some SNPs show little variation in allele frequencies around the world – a low F_{st} – while others show a great deal of variation in allele frequencies – a high F_{st}. Such variation in F_{st} is expected for loci independently subject to random genetic drift through the identical historical demography. However, it is not immediately obvious why this distribution is skewed. Other studies of multiple loci in smaller numbers of ethnic groups also show a similar skewed distribution (Stephens *et al*., 2001a; Bamshad and Wooding, 2003). This distribution may have been affected by the complex, biased ascertainment of the SNPs, as noted above. That is an area to be investigated. The global F_{st} for STRPs is noticeably smaller (Rosenberg *et al*., 2002), both because the higher mutation rates will tend to damper the effects of random genetic drift and because the higher heterozygosities of STRPs impose algebraic limits on F_{st}.

3.3. Global pattern of linkage disequilibrium

LD is the term usually used to describe nonrandom combinations of alleles at multiple sites on chromosomes in the population. LD is not an all-or-nothing phenomenon but ranges from nearly random combinations of alleles to complete

correlation such that a given allele at one site always occurs with a specific allele at another site and vice versa. A variety of statistics can be used to quantify the level of nonrandomness in any segment of DNA (Devin and Risch, 1995; Zhao *et al*., 1999). As one can imagine from differences in haplotype frequencies, these statistical measures, which are based on those haplotype frequencies, show differences in the magnitude of LD among populations from different parts of the world. The general pattern is random or nearly random association of alleles in populations within Africa, higher values and significantly nonrandom allelic associations in Eurasian populations, and even more nonrandomness in Native American populations (Tishkoff and Kidd, 2004). A more precise summary is difficult to formulate because recombination rates differ by orders of magnitude across segments of DNA such that loci differ considerably in strength and pattern of LD and recent demography of individual populations can have a significant effect.

3.4. Population similarities based on DNA sequence variation

On a global basis, there are many methodologies available for studying genetic similarity among populations. All of them show that populations that are geographically closer have allele and haplotype frequencies that are more similar. One study of allele frequencies of 377 STRPs in 52 populations (Rosenberg *et al*., 2002) showed geographic clustering of the populations but the Central Asian populations showed a gradient between Europe and East Asia. Other analyses of these data have emphasized more strongly the clinal aspects of the allele frequency data (Bamshad *et al*., 2004; Serre and Paabo, 2004). Another study used primarily SNPs and haplotypes thereof to define >600 alleles in 37 populations (Tishkoff and Kidd, 2004). These data were used to generate a tree diagram of the populations (Figure 1) that shows both geographic clustering and a clinal pattern extending from Africa through Europe and Central Asia and then extending in two separate branches, one to East Asia and the Pacific and the other to the Americas. The large bootstrap values basically define four strong clusters: the African populations (including African Americans), the European populations (including European Americans) and middle eastern populations along with one population from northwestern Siberia (Komi), the East Asian populations, and the Native American populations. Several populations are definitely outside of those four clusters: the Ethiopian Jews, the Khanty from northwestern Siberia, the Yakut from northeastern Siberia, the Micronesians, and the Nasioi Melanesians. Were there more geographically intermediate populations, the clustering would not be so evident, as seen in such analyses as Bamshad *et al*. (2004).

The out of Africa model first supported molecularly by studies of mitochondrial DNA (Cann *et al*., 1987) is supported by most of these data except the heterozygosity data on SNPs. The model can be described as follows. Genetic variation had already accumulated in anatomically modern humans in Africa between 150 000 years BP and 100 000 years BP. That variation was not evenly distributed across the continent, as expected in an isolation-by-distance model, but considerable randomness among closely linked sites had accumulated. That

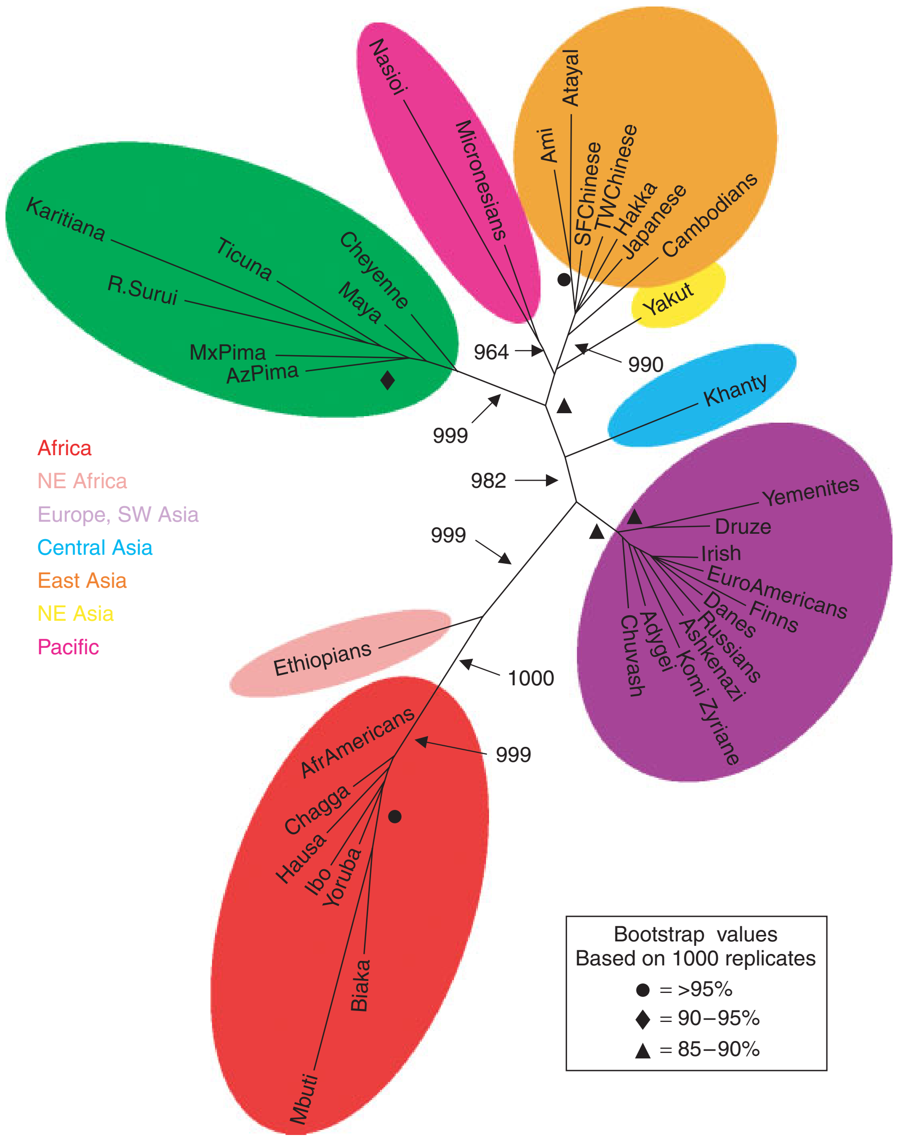

Figure 1 A least-squares tree structure representing the genetic distances among 37 populations. Eighty independent loci (41 as multiallelic haplotypes, 36 biallelic, and 3 STRPs) with about 600 statistically independent alleles were used to calculate the genetic distances. While the assumptions underlying the calculations and representation do not allow this to be interpreted as a precise representation of evolutionary history, the main structure of the tree corresponds to the recent African origin model with increasing genetic distance as early populations migrated away from Africa. SF: San Francisco; TW: Taiwan; MX: Mexico; AZ: Arizona; R: Rondonian. The arrows with actual bootstrap values (out of 1000) indicate segments along the backbone of the tree with high consistent support among the genetic loci. Other large bootstrap values are indicated with symbols: circles, >95%; diamonds, 90–95%; triangles, 85–95%. (Reproduced from Tishkoff and Kidd (2004). © Nature Publishing Group)

variation and low levels of LD still exist in most modern African populations. About 100 000 years BP, some people from Northeast Africa migrated into Southwest Asia. Since the people who migrated originated from the populations of Northeast Africa, they sampled from that already partially diverged gene pool, and the sampling error (founder effect) of the migration accentuated the loss of variation. Only a fraction of the genetic variation in Africa as a whole was represented in that initial "non-African" population. It was that population in Southwest Asia that then increased in numbers and spread geographically to occupy all of Eurasia and Australo-Melanesia by about 40 000 years BP with progressive loss of variation in the populations through accumulating genetic drift as they spread eastward and eventually reached far East Asia. At some time more recent than 40 000 years BP, some of the populations from Siberia migrated to the Americas and expanded to occupy first North and then South America. Additional variation was lost during that colonization but the effect was less than that associated with the initial expansion out of Africa. At all of those stages where variation was lost, nonrandomness (LD) increased among the remaining variants in small segments of DNA (Figure 2). Thus, much of the LD seen in non-African populations is the result of the founder effect associated with the expansion out of Africa. An abstract, artistic rendition of this model can be found at **http://info.med.yale.edu/genetics/kkidd/point.html**.

During most of the century since the beginning of scientific study of genetic variation in humans, there was no clear explanation for the differences among populations. Indeed, the global pattern was not clear. The huge numbers of DNA sequence variants now being studied have changed that. The global pattern of DNA sequence variation we see illustrated in the tree analyses (Figure 1) and in principal components analyses (Kidd *et al*., 2004) is a reflection of the early history of modern humans expanding out of Africa and occupying the rest of the world. Our early history as a species is responsible for the broad-stroke distribution of DNA sequence variation.

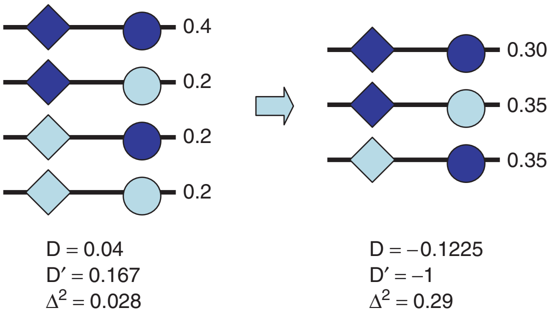

Figure 2 Consider the diamond and circle loci with light and dark alleles at each and haplotype frequencies as indicated. If random drift causes one haplotype to be lost, as indicated by the arrow, it is possible for the individual allele frequencies to change very little (dark alleles increased in frequency from 0.6 to 0.65) while the nonrandomness, indicated by several standard disequilibrium statistics (Devin and Risch, 1995), has increased greatly

Specialist Review

Reliability and utility of single nucleotide polymorphisms for genetic association studies

C. Leigh Pearce

1. Introduction

Most common diseases and disease-related quantitative traits (such as body weight or blood pressure) are complex genetic traits (*see* Article 58, **Concept of complex trait genetics**, Volume 2), under the influence of multiple genetic and nongenetic factors. Efforts to understand the contribution of genetic variation to complex traits have increased exponentially since the late 1990s, as the completion of the Human Genome Project (*see* Article 23, **The technology tour de force of the Human Genome Project**, Volume 3 and Article 24, **The Human Genome Project**, Volume 3) and related efforts have greatly increased the feasibility of these pursuits. Single-nucleotide polymorphisms (SNPs) are by far the most common type of genetic variation in the human genome (*see* Article 68, **Normal DNA sequence variations in humans**, Volume 4), with estimates of 11 million SNPs with a frequency of 1% or greater (Reich *et al*., 2003; Kruglyak and Nickerson, 2001). The first comprehensive assessment of coding region variation revealed that a typical gene has two missense and two silent SNPs, and the overall density of SNPs was consistent with current expectations of a common SNP every 300 bp (Halushka *et al*., 1999; Cargill *et al*., 1999). This was followed shortly by the formation of The SNP Consortium (TSC), which by 2001 had submitted more than 1.4 million SNPs located throughout the genome to the public dbSNP database (**http://www.ncbi.nlm.nih.gov/projects/SNP/**) (Sachidanandam *et al*., 2001). The efforts of the Human Genome Project and The International Haplotype Map Project

(HapMap) (**www.hapmap.org**) have added to the availability of SNP data, and now there are more than 10 million in the public database with genotype frequency available for a substantial proportion (The International HapMap Consortium, 2003). Furthermore, studies have shown that most SNPs are strongly correlated with other neighboring SNPs, meaning that the overwhelming majority of undiscovered common SNPs are reflected by those currently in dbSNP.

Association studies, which are discussed in more detail below, use SNPs as genetic markers, and test whether an allele is more common in cases than in controls (or in individuals with higher trait values vs. lower trait values). However, results of these studies have been inconsistent (Hirschhorn *et al*., 2002). To help understand how SNPs can be effectively used for association studies, we consider two aspects of reliability of SNP-based association studies. First, we consider whether the SNPs in the dbSNP database are in fact valid and useful for association studies. Second, we detail the reasons why association studies with these SNPs have been so inconsistent, and the possible routes to minimize the inconsistency.

2. Comprehensiveness, validity, and frequencies of SNPs in the public dbSNP database

Genetic association studies are a potentially powerful tool to identify variants that contribute to common disease susceptibility or other disease-related traits (Risch and Merikangas, 1996; Hirschhorn and Daly, 2005; *see also* Article 59, **The common disease common variant concept**, Volume 2). There are two major approaches for using SNPs in association studies (discussed in more detail below): a direct approach to association studies, in which putative functional SNPs are tested for association with the phenotype, and an indirect approach, which exploits correlations (linkage disequilibrium, LD) between nearby SNPs and uses a subset of SNPs that capture the vast majority of the common variation in a region (*see* Article 17, **Linkage disequilibrium and whole-genome association studies**, Volume 3 and Article 74, **Finding and using haplotype blocks in candidate gene association studies**, Volume 4). Regardless of the approach used, the validity and comprehensiveness of SNPs from the public SNP database (dbSNP) is critical in order to ensure that resources, both labor and money, are used wisely for genotyping and disease-associated regions are not missed because of the relevant SNPs being absent from the database.

2.1. Reliability of SNPs in dbSNP

The public database (dbSNP) currently contains over 10 million SNPs. Although essentially all of the SNPs were discovered by resequencing the same stretch of DNA in different chromosomes, the details of their ascertainment varies. The number of chromosomes used in the SNP discovery process has ranged from two to hundreds, and individuals from a variety of different ethnic groups have been used. These differences in ascertainment affect SNP frequencies because of human

history. Until recently, the human population was actually quite small (about 10 000 individuals), so population genetics (*see* Article 1, **Population genomics: patterns of genetic variation within populations**, Volume 1) predicts that most SNPs identified by comparing two chromosomes will be common (allele frequencies well over 1%). Indeed, this prediction has been verified (Gabriel *et al*., 2002). SNPs seen twice out of four chromosomes ("double hit") are even more common on average. By contrast, studies that resequence a large number of chromosomes to identify SNPs (deep resequencing) will identify not only the common SNPs but also rare SNPs. Indeed, population genetics also predicts that SNPs seen once in a study that has examined hundreds of chromosomes will have a true frequency of well under 1/1000.

The ethnicity of the samples used for SNP discovery also affects their allele frequencies in different populations (*see* Article 2, **Modeling human genetic history**, Volume 1). In particular, because non-African populations are derived from an ancestral African population (Tishkoff and Williams, 2002), populations with recent African ancestry have more diversity than other populations, so SNPs identified in these populations will sometimes be monomorphic in other populations. Finally, because none of the algorithms used to identify SNPs from sequence data are perfect, some apparent SNPs will in fact turn out to be sequencing artifacts. Although the overall reliability of these 10 million SNPs is high, some are false-positives, some are vanishingly rare, and others are private to specific populations.

A number of groups have reported the rate of "validation" of SNPs – that is, when SNPs from dbSNP are genotyped in a particular population, how often are they observed to be polymorphic? A true estimate of the false-positive rate requires genotyping the individual(s) in whom the SNP was discovered. If the individuals used for SNP discovery are not assayed, rare SNPs (or SNPs that are private to particular populations) may appear to be false-positives because they are monomorphic in the genotyped population. The International SNP Map Working Group was the first to provide a dense set of markers across the human genome, with an average density of one SNP ever 1.9 kb (Sachidanandam *et al*., 2001). This group validated a subset of 1500 SNPs that they discovered by genotyping them in the same population in which they were identified. They found that 4% of their SNPs were false-positives (Sachidanandam *et al*., 2001). Similarly, Reich *et al*. (2003) found through a deep resequencing effort that 98% of the TSC SNPs were validated in the population in which they were discovered.

When 3738 of these SNPs were genotyped in four other populations, 89% were polymorphic in at least one population (Gabriel *et al*., 2002), confirming that these SNPs, which were discovered largely by comparing two chromosomes, are generally common enough to be detected at appreciable frequencies. By contrast, other studies (Carlson *et al*., 2003; Cutler *et al*., 2001) have reported that SNPs from dbSNP are polymorphic at much lower rates. The lower rates result from a combination of including SNPs ascertained by different methods (and hence with different frequencies), plus most likely some rare SNPs were falsely thought to be monomorphic (Carlson *et al*., 2003).

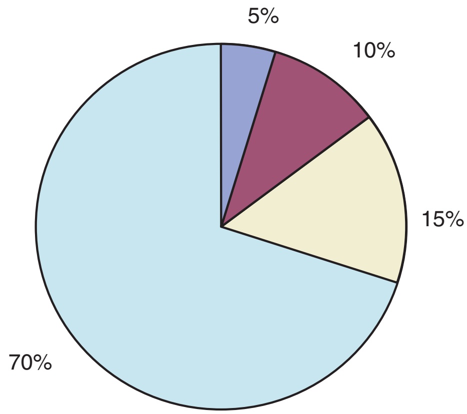

Figure 1 Approximate fractions of SNPs in dbSNP (2004) that are false-positive (blue), rare in all populations (purple), or common (>1%) in some (beige) or all populations (green). Estimates are based on Gabriel *et al*., (2002), Reich *et al*. (2003), and unpublished observations by our groups and others (D. Altshuler, S. Gabriel, and M. J. Daly, personal communication)

Most of the SNPs in dbSNP were discovered by an automated algorithm identical or similar to the method used by the International SNP Map Working Group (Sachidanandam *et al*., 2001), suggesting that the false-positive rate in dbSNP is likely to be near 4%. This relatively low false-positive rate is encouraging, however, it is important to remember that the rate at which true positive SNPs will be polymorphic in any particular population depends on the method by which the SNPs were ascertained, and the ethnicity and size of the population(s) tested (Cavalli-Sforza *et al*., 1994). False-positives aside, how often will SNPs be common across populations, given the known differences in allele frequencies across populations (Cavalli-Sforza *et al*., 1994)? Gabriel *et al*., (2002) found that only 59% of the SNPs they tested were variable in all four of their populations. Only 52% of the common SNPs assayed by Carlson *et al*. (2003) were common in both of the populations they studied. As expected, most of the SNPs that were found only in one major population group were specific to populations with recent African ancestry. Figure 1, which is derived from these and similar data, displays the approximate current status of the SNPs in dbSNP.

Efforts can be made to improve the likelihood that a SNP genotyped as part of an association study is polymorphic. Importantly, many of the SNPs in dbSNP are being computationally or experimentally validated, and allele frequencies will be available for a substantial fraction (such frequency data is readily available from dbSNP and the HapMap). Also, utilizing SNPs that have been identified by more than one investigator also greatly increases the likelihood of those SNPs being polymorphic in the population under study – since rare SNPs are unlikely to have been seen twice and the identical sequencing artifact leading to a false-positive SNP is unlikely to be replicated in multiple labs. For example, in the study by Carlson *et al*. (2003), approximately 85% of SNPs that were reported by more than one investigator were polymorphic. Identifiers representing the number of times a SNP has been discovered and its validation status are available in dbSNP.

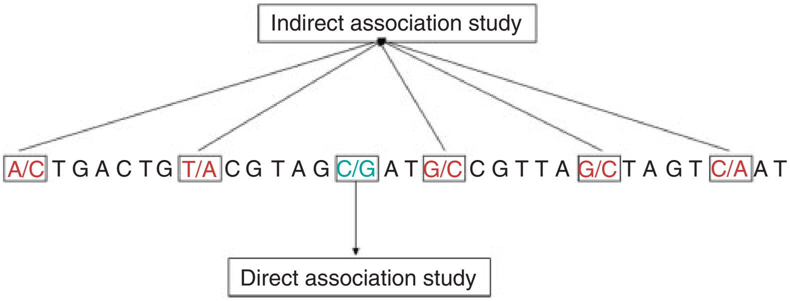

Figure 2 The figure shows six SNPs across a genomic region, five in red without functional consequence to the protein and one in blue that is functional. In a direct association study only the SNP in blue would be tested, whereas in an indirect association study, some of the five SNPs in red would be tested in an effort to mark the functional SNP

2.2. *SNPs for indirect and direct association studies*

As mentioned above, SNPs can be used for association studies in two complementary manners, as shown in Figure 2. They can be used indirectly as genetic markers, which will be effective if there is sufficient correlation (LD) between the typed SNP and a nearby causal variant, or if the typed SNP is itself causal. Alternatively, efforts can be made to try to directly identify and genotype those SNPs that are likely to be functional and therefore causal, without having to rely on LD.

The underlying assumption of an indirect association study is that the SNPs that are genotyped serve as effective proxies for other unmeasured, potentially causal SNPs. For this approach, the key question is then, "Can SNPs in the public database capture enough of the underlying diversity across the genome"? The simple answer, for common genetic variation, is that the vast majority of variation can probably be captured using this approach (Hirschhorn and Daly, 2005). Recent resequencing efforts surrounding the encyclopedia of DNA elements (ENCODE) and HapMap projects have suggested that, in populations with recent European ancestry, 80–90% of the estimated 11 million common SNPs in the human genome can be well captured by the SNPs that are already in public databases, suggesting that if the LD relationships between SNPs are known in a population, indirect association studies can be carried out effectively (*see* Article 12, **Haplotype mapping**, Volume 3 and Article 73, **Creating LD maps of the genome**, Volume 4). Indeed, a significant majority of SNPs with frequencies above 10% are already in the database (D. Richter, S. Gabriel, D. Altshuler, personal communication); rarer SNPs (particularly those below 5%) are less well represented, although long-range haplotypes of tag SNPs may help capture these rare SNPs (Lin *et al*., 2004). How large a set of "tag SNPs" is required to efficiently capture the remaining common variation has yet to be determined, but will depend on the population being studied – populations with recent African ancestry will require more SNPs because they have shorter average extents of LD and greater haplotype diversity within regions of LD (Gabriel *et al*., 2002; Reich *et al*., 2002; Crawford *et al*., 2004). The HapMap is designed to provide extensive SNP frequency data on multiple ethnic groups in an effort to

fill in many of these gaps (The International HapMap Consortium, 2003). The current HapMap goals are for 3–5 million SNPs to be typed in four populations representing three major continental groups: Han Chinese and Japanese, Yoruba from Nigeria, and European-Americans. Because of this fairly broad representation in the study, tag SNPs chosen on the basis of data from these populations may well do a good job of representing a diverse set of populations worldwide, a hypothesis supported by our group's unpublished observations. However, the general utility of tag SNPs selected on the basis of HapMap data needs to be assessed for each of the major population group that is used in association studies.

In the direct association approach, certain classes of SNPs are hypothesized to have a higher prior probability of influencing disease risk. These types of SNPs include nonsynonymous SNPs (nsSNPs) and SNPs that fall in evolutionary conserved regions (ECRs).

Nonsynonymous SNPs are both less abundant and have lower average allele frequencies than other SNPs, because many potential changes to the coding sequence of genes are evolutionarily deleterious (Cargill *et al*., 1999). The abundance of nsSNPs is 30% less than would be expected under a neutral model, and only 41% of nsSNPs have a frequency of 5% or greater compared with 61% of noncoding variants (Cargill *et al*., 1999). Because they are on average rarer than typical SNPs, nsSNPs are relatively underrepresented in dbSNP, and identifying all common (>1%) nsSNPs would require a substantial focused effort.

Because nsSNPs alter the encoded amino acid, they are believed to be more likely to alter the function of the gene product in important ways. It has been suggested that association studies should focus on these types of variants (Botstein and Risch, 2003). This argument is based on the allelic spectrum of single gene disorders, although there is reason to suggest that regulatory variants may play an equally important role in common polygenic diseases and quantitative traits (Reich and Lander, 2001; Hirschhorn and Daly, 2005). In addition, not all nsSNPs are created equal, and a number of mechanisms have been put in place to facilitate identifying nsSNPs that have a higher probability of influencing the structure or function of a gene (Ng and Henikoff, 2002; Ng and Henikoff, 2003; Conde *et al*., 2004). One such method is SIFT (Sorting Intolerant From Tolerant), which takes user-supplied data on the nsSNPs and then links to a series of publicly available databases to predict whether the nsSNP is tolerant (less likely to be damaging to the protein) or intolerant (more likely to be damaging to the protein) (Ng and Henikoff, 2002; Ng and Henikoff, 2003). Zhu *et al*. (2004) used SIFT to retrospectively assign 46 candidate cancer nsSNPs in 39 genes to a tolerance index. The investigators then compared the odds ratios associated with the nsSNP and the cancer outcome to the tolerance index. Zhu *et al*. (2004) found a strong relationship between the tolerance index and the magnitude of the cancer-nsSNP odds ratio ($p = 0.002$). However, the false-positive and false-negative rates of this and related algorithms remain unknown.

SNPs that fall in noncoding genomic regions conserved across species may also be more likely to be functionally relevant (Nobrega *et al*., 2003; Frazer *et al*., 2004). A number of tools have been put in place to identify these ECRs, such as the ECR Browser (**http://ecrbrowser.dcode.org/**) and VISTA (**http://www-gsd.lbl.gov/vista/index.shtml**), both of which can align sequences across multiple

species. Selecting SNPs that fall into these regions may increase the probability of finding an association with disease risk, but it is much more difficult within ECRs than it is within coding regions to distinguish those variants that are functionally important.

In summary, abundant SNPs are present in the dbSNP database. Most of these are "real" SNPs, although their frequency will vary by population studied. There are sufficient SNPs to embark on indirect association approaches, and the HapMap is generating data to allow selection of sets of SNPs for this approach. Direct tests of putative functional SNPs are also possible, but more work would be required to build a catalog of potentially functional SNPs for use in association studies. The reliability of association studies is discussed in the next section.

3. Application of SNPs for association-based studies

Now that the public database contains enough SNPs to carry out comprehensive and meaningful genetic association studies, what are the challenges in the interpretation of these types of studies? Replication of association study results has proved challenging; a recent review of association studies showed that only 6 of 162 associations were very consistently replicated (Hirschhorn *et al*., 2002). There are three main classes of reasons why association studies fail to replicate: true variability in the populations studied (heterogeneity), false-positives, and false-negatives (see Figure 3). Each of these is discussed below.

3.1. Heterogeneity

A frequently invoked but rarely proven explanation for inconsistency in genetic studies is heterogeneity between populations. In other words, it is proposed that the populations under study are different in important ways that make the association much stronger in some of the populations (Figure 3). For example, there could be environmental factors (such as diet) that both vary between populations and modify the association between the genetic variant and disease susceptibility. Similarly, there could in theory be genetic modifiers that vary substantially between

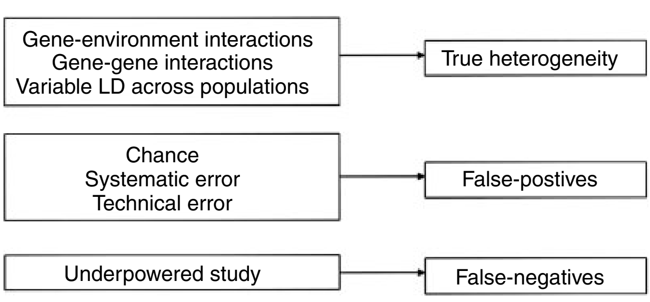

Figure 3 The figure shows the three situations leading to inconsistency in genetic association studies on the right-hand side, and possible causes on the left. See text for details

populations and lead to variability in association results. Heterogeneity could arise if the variant that is genotyped is in LD with the causal allele, and the strength of the LD varies across populations. Variable LD is in theory easy to address by comprehensive surveys of variation in genes showing evidence of association. However, demonstrating gene–environment and gene–gene interactions requires knowledge of the modifiers that differ between populations, and extremely large sample sizes will be usually required to prove convincingly that gene–gene and gene–environment interactions are important for a given association. Finally, phenotypic heterogeneity could also account for differences in findings across populations. If disease classification changes over time, or if diagnostic criteria are inconsistent or subjective, then differences in association results could be observed.

3.2. False-positive associations

Recent surveys have estimated that at least 70 to 80% of reported associations are false-positives (Ioannidis *et al*., 2001; Lohmueller *et al*., 2003). False-positives can occur as a result of chance fluctuations that are enhanced by inadequate statistical control and interpretation, systematic biases in study design, or systematic bias due to technical issues, each of which can result in the expenditure of valuable resources in terms of both money and time.

3.2.1. Chance

Chance fluctuations are by far the major source of false-positive associations, mainly because of the criteria for declaring a "positive" association. The standard measure for determining whether any given finding is the result of chance is the p-value. By definition, a p-value is the probability of observing the study result or one more extreme than that observed when the null hypothesis is in fact true. Historically, associations between a SNP and a phenotype are considered statistically significant if the p-value is 0.05 or less, regardless of the number of SNPs that were tested. A p-value of 0.05 means, however, that one out of 20 tests will be positive by chance alone. At the extreme, if one tested the entire range of 10 million common SNPs throughout the human genome, a p-value of 0.05 would mean that 500 000 associations would be observed simply due to chance. Multiple phenotypic tests would further increase the number of p-values below 0.05. Thus, the threshold of 0.05, although standard throughout the scientific literature, is inadequate given the number of hypotheses that could be tested in an association study, compared with the number of variants in the genome that are actually causal, which is likely a very small number. The false-positive results will dwarf any truly causal associations, therefore making all of the results uninterpretable. What then is the appropriate statistical threshold for determining if an association is simply due to chance because so many hypotheses were tested?

The issue of multiple hypothesis testing and related adjustment of the p-value for association has been considered by many investigators (Thomas and Clayton, 2004; Wacholder *et al*., 2004; Cardon and Bell, 2001; Dudbridge and Koeleman, 2004; Colhoun *et al*., 2003). One approach to reduce type I errors is a Bonferroni correction that is simply computed by dividing the standard statistical

significance level of 0.05 by the number of tests performed. The Bonferroni correction is somewhat overly conservative, because it assumes that all of the tests are independent (Thomas and Clayton, 2004), but quite often, many of the tests are correlated (as when multiple SNPs that are in LD are tested). To estimate a Bonferroni correction for surveying the entire genome, Risch and Merikangas (1996) advocated a p-value threshold of 5×10^{-8} (which is the equivalent of a p-value of 0.05 after adjusting for the assumed one million tests). Calculating the exact number of tests is problematic, but one can still estimate the sample sizes required to meet this conservative threshold. For alleles with strong effects on disease risk, even this stringent adjustment does not demand unreasonably large sample sizes. For example, assuming a log additive mode of inheritance, a minor allele frequency of 20%, 80% power, and an odds ratio of 3.0, only 165 cases and 165 controls would be required. But, much larger sample sizes are required for alleles with more modest effects. If the odds ratio were only 1.3, more than 3000 cases and 3000 controls would be required. Similarly, rarer alleles require larger sample sizes as well. Because many alleles that affect complex traits are likely to have odds ratios of 1.5 or less (Lohmueller *et al*., 2003), very large sample sizes will be needed to achieve statistical significance that withstands a genome-wide correction. However, it is important to note that several associations have already achieved these stringent levels of significance (Hirschhorn and Daly, 2005).

Other approaches, such as permutation testing, that can take into account non-independence of different tests, may thus be valuable (Dudbridge and Koeleman, 2004). Regardless of the method used, however, it is helpful for any particular study to include an accurate assessment of the likelihood of achieving the observed p-value by chance, given the tests that were performed in that study. A Bayesian method can also be used to help interpret how much a particular study strengthens support for an association. This approach is informed by our understanding of the disease process and the existing evidence of a disease-SNP association, that is, what is the prior probability of the SNP being associated with the phenotype? Wacholder *et al*. (2004) described the "false-positive report probability" (FPRP) as the probability that there is no true association despite a statistically significant finding. The FPRP is determined on the basis of the size of the observed p-value, the power of the study, and the prior probability of an SNP-disease relationship. This approach is extremely appealing because each observed association can be evaluated on its own merits, however, the determination of an acceptable FPRP is rather arbitrary and specifying the prior probability for each SNP-disease relationship is also challenging. Regardless of these issues, the FPRP can be determined for a range of priors allowing the investigator to provide this information for others to evaluate. Sample sizes needed to achieve a low FPRP will be comparable to those needed for a Bonferroni correction for having tested a sizable fraction of the genome. Thus, regardless of the method used to evince convincing statistical support for an association, large sample sizes will usually be required.

3.2.2. Systematic bias

The above section considers the false-positive rates for association studies in the absence of any systematic bias toward positive results. However, if such a

bias exists, the false-positive problem will be exacerbated. The primary potential source of systematic bias toward false-positives in genetic association studies using unrelated subjects is population substructure (*see* Article 75, **Avoiding stratification in association studies**, Volume 4). Although some researchers believe that population substructure is not likely to be a major problem (Wacholder *et al*., 2002; Wacholder *et al*., 2000), others recognize its potential role in false-positive association study results (Thomas and Witte, 2002; Gorroochurn *et al*., 2004). Population substructure refers simply to confounding by ethnicity, a situation in which both allele frequencies and disease incidence are related to ethnicity and a spurious association between genotype and disease can therefore be observed (Lander and Schork, 1994; Ewens and Spielman, 1995). Three situations are believed to give rise to this type of bias in association studies: gross population stratification, cryptic relatedness, and population admixture (Pritchard *et al*., 2000a; Pritchard and Donnelly, 2001).

Although the terms stratification, cryptic relatedness, and admixture are often used to describe similar situations, in this context we will refer to gross population stratification as the existence of multiple ethnically heterogeneous groups all of which are grossly categorized together in the context of a disease that varies in its frequency by ethnic group. In the most basic sense, this would include ignoring broad ethnic categories such as White and Asian, and grouping them together without consideration for ethnicity. This situation is addressed easily by utilizing self-reported ethnicity as a means for classification. Any allele that varied in its frequency between these two ethnic groups would appear associated with disease, however, simple adjustment for ethnicity in any statistical analysis would eliminate this type of confounding.

More controversial is the situation of cryptic relatedness (often called cryptic or mild stratification) in which there are potential differences in allele frequencies between subpopulations within a grossly homogeneous population that shares the same ethnic self-identification (Pritchard *et al*., 2000a; Pritchard and Donnelly, 2001). For example, cases may be more closely related to each other than are controls, because they by definition share many of the genetic factors that contribute to their disease status. Because even homogeneous populations may in fact have gradients of allele frequencies (Helgason *et al*., 2005), cryptic relatedness may result in uneven distributions between cases and controls not only of causal alleles but also of other noncausal alleles, thereby leading to false-positive associations. Mild stratification can also occur when cryptic differences in ethnicity track with differences in exposure to nongenetic susceptibility factors, with the end result that one subgroup is over represented in the cases. If there are genetic markers that are more common in the subgroup, false-positive associations could ensue. Empirical studies have shown that mild stratification cannot be ruled out, even in studies of apparently homogeneous populations (Freedman *et al*., 2004), and we have recently demonstrated a false-positive association due to mild stratification in a self-described Caucasian US population (Campbell *et al*., 2005). However, it is not clear how serious a problem stratification will be in practice.

On the other hand, recent admixture, which occurs when two or more ethnically diverse groups mix, has been shown to cause false-positive associations. In this case, the recent admixture results in a group with varying levels of ancestry from

each of the two ancestral groups. For example, the proportion of European ancestry among African-Americans, an admixed population, is estimated to range from 11.6 to 22.5 depending on the geographic region of the United States. (Parra *et al*., 1998). If, for example, the risk of disease increases with increasing European ancestry, individuals with higher European ancestry will be overrepresented in cases, and any of the many alleles that are more common in European populations than in African populations would appear to be associated with disease.

Two methods, genomic control (Devlin and Roeder, 1999; Devlin *et al*., 2001; Reich and Goldstein, 2001) and structured association (SA) (Pritchard *et al*., 2000a; Pritchard and Rosenberg, 1999), have been developed to address the issue of population substructure in genetic association studies by using unlinked markers across the genome. Genomic control is based on the assumption that random markers throughout the genome that are unlinked to disease loci should not be associated with disease in the situation of no population substructure (Devlin and Roeder, 1999; Reich and Goldstein, 2001). If population substructure is present, however, the chi-square test statistics for these unlinked markers will be higher than the expected null distribution. The amount of this increase can then be quantified and converted into an inflation factor (λ) for the chi-square test statistic of interest, namely, that obtained from testing the association between disease and a candidate SNP. SA is based on using unlinked markers to categorize study subjects into subpopulations (Pritchard *et al*., 2000b; Pritchard and Donnelly, 2001; Pritchard and Rosenberg, 1999). The assumption of this approach is that although there is heterogeneity within a population, the subgroups can be identified and categorized into discrete groups based on genotype data. Originally, this method only provided a method to determine whether or not population substructure was present, but with no mechanism to deal with the information (Pritchard and Rosenberg, 1999). This was extended to allow for the estimate of genotype effect after adjusting for population substructure (Pritchard *et al*., 2000a; Hoggart *et al*., 2003). Publicly available software can be used to implement the population structure categorization algorithm (**http://pritch.bsd.uchicago.edu/**). Freedman *et al*., (2004) tested for population substructure among the 11 epidemiologic studies they evaluated using the SA method as well. On the basis of their original sample size and number of unlinked loci tested, they found no statistically significant evidence of population substructure, despite λ values that could be as high as 4.0, which can greatly increase the chances of false-positive association (Marchini *et al*., 2004).

The lack of significant evidence of substructure in these empirical studies could mean that no such substructure exists, or that not enough markers were typed to detect the substructure. The number of unlinked loci that need to be tested to confidently determine λ or to assign individuals to a population subgroup is unclear. Estimates of the number of loci vary widely, but are likely to be well over 100, depending on the precision with which assignment to a population group is made or λ is estimated, as well as the allele frequency differences across populations, the number of subpopulations in the study group, and the ability of markers to distinguish between the subpopulations (Pritchard *et al*., 2000a; Pritchard and Rosenberg, 1999; Hoggart *et al*., 2003; Turakulov and Easteal, 2003; Falush *et al*., 2003; Hao *et al*., 2004; Rosenberg *et al*., 2003). As genotyping costs are reduced, genotyping 100 or more loci in any genetic association study of

unrelated individuals will become routinely feasible and should be conducted to minimize the likelihood of a false-positive finding.

3.2.3. Technical errors

Errors in genotyping are another potential source of false-positives in association studies, especially family-based studies. Genotyping error is considered to be random and therefore should result in bias toward the null, but Mitchell *et al*. (2003) have shown that in the context of the transmission/disequilibrium test (TDT) this is not necessarily the case. These investigators found that genotyping error that goes undetected will result in apparent overtransmission of the common allele leading to incorrect associations (Mitchell *et al*., 2003). This result is in concert with those of Gordon *et al*. 2001, who also found that genotyping error is a reason for false-positives in TDT-based SNP studies. Missing data can also increase the false-positive rate in family-based studies (Hirschhorn and Daly, 2005). By contrast, in case–control studies using SNPs, undetected random error or missing data will result in a loss of power to detect an association (Gordon and Ott, 2001).

A number of other nonrandom laboratory-based errors are also of concern, but are easier to control. For example, if cases and controls are genotyped separately, rather than intermingled on genotyping plates, then any increased genotypic dropout or error that is plate-specific will be nonrandom with respect to disease status – leading to a biased association finding. This problem can be avoided by simple planning of plate layouts and quality control procedures.

3.3. False-negatives

Finally, false-negative studies also are an important contributor to the inconsistency in association reports (Figure 3). Recent meta-analyses of association studies have shown that most validated associations have modest odds ratios of 2 or less (indicating that carriage of the risk allele increases the risk of disease by less than twofold) (Ioannidis *et al*., 2001; Lohmueller *et al*., 2003). Modest odds ratios such as these require large sample sizes (in the thousands) to achieve p-values below 0.05; even larger samples are required to meet more stringent statistical thresholds. Because most association studies have not even approached the required sample sizes, most have not had power to achieve even nominal significance ($p < 0.05$), so false-negative studies have been rampant for most validated associations (Lohmueller *et al*., 2003).

The problem of replicating valid associations is complicated by the fact that the first "significant" report of an association between an SNP and phenotype almost invariably has an inflated odds ratio as a result of the "winners curse". Because of this phenomenon, a description of which appears in Lohmueller *et al*. (2003), actual odds ratios are even more modest than they first appear, so replication studies will require even larger sample sizes than would be estimated based on the first published odds ratio. These large sample sizes can be achieved either in individual studies, or, with appropriate care, through meta-analysis. Thus, just as

rigorous statistical thresholds and large sample sizes offer a way to minimize false-positives, large sample sizes can reduce the contribution of false-negative studies to the inconsistency of association studies.

Although there are considerable challenges for conducting SNP-based association studies, sound study design and interpretation can lead to reliable results. False-positive results due to either chance, population substructure, or systematic technical errors can be minimized by large sample sizes combined with appropriate statistical thresholds, consideration of the possibility of admixture, and rigorous laboratory protocols. False-negatives, particularly in the replication stage of an association, can also be greatly reduced by large sample sizes and careful interpretation. However, the true reliability of association studies will only become apparent after the genome has been surveyed for association in large samples (Hirschhorn and Daly, 2005).

4. Summary

SNP databases currently contain enough reliable, validated, and useful SNPs to adequately assess common genetic variation for a role in disease. Establishing a complete catalog of potentially functional SNPs will still require additional effort, as will assembling the tools to survey rare variation. The rapidly accumulating data in the human Haplotype Map will permit LD-based association studies of common variants. The reliability of these association studies will be improved by increased statistical rigor and increased sample sizes.

Specialist Review

Pharmacogenetics and the future of medicine

Alun D. McCarthy, James L. Kennedy and Lefkos T. Middleton

Genetics Research, GlaxoSmithKline Research & Development, Uxbridge, UK

1. Introduction: a historical perspective

The unprecedented international research efforts over the last 20 years in identifying polymorphisms that are either causative of, or affect the susceptibility to, human disease, are beginning to have a visible and significant impact on medical care. First, the identification of causative mutations of monogenic diseases and subsequent phenotype–genotype correlation studies in the late 1980s and 1990s have resulted in the definition of their nosological boundaries (i.e., disease classification). The subclassification for many of these diseases has been clarified, and knowledge of their heterogeneity and pathogenesis has been realized (Weatherall, 2001). Prevention programs are already widely used around the world, and therapeutic attempts have become possible for diseases such as Huntington's disease, thalassemias, and muscular dystrophies. The efforts to sequence the human genome have resulted in the identification of most of the DNA sequence. This information, coupled with the more recent availability of high-density single-nucleotide polymorphism (SNP) maps and other tools in genomics, bioinformatics, RNA expression, and proteomics, have accelerated the application of these new tools to complex diseases and interindividual variability to drug response. For the latter, the impact is upon both drug efficacy and drug safety. The promise of the "new genetics" lies in its potential to provide insight into each individual's genetic makeup, infer susceptibility to not only a given disease but also specific kinds of symptoms (e.g., vas deferens pathology in cystic fibrosis), and to enable better therapeutic decision making. Overall, this knowledge of DNA variations can contribute to well-informed medical action. Furthermore, the recent availability of a number of imaging and molecular translational technologies allows for a more accurate diagnosis of the individual's physiological and phenotypic status. These technologies include imaging techniques that go far beyond anatomical structure, to real-time physiological processes in vivo revealing correlations with behavior (such as functional MRI; Hariri and Weinberger, 2003). What was recently remarkable is now routine – pharmacological events can be observed in vivo using MR spectroscopy, PET, and SPECT. Human biological processes can be further illuminated by an increasing

armamentarium of molecular tools exploring transcriptomic expression, proteomic and metabolomic phenomena (Campbell and Ghazal, 2004; Plumb *et al*., 2003).

The application of these physiologic and genomic technologies will provide greater insight into the heterogeneity that clearly exists within our current diagnostic nosology and a more accurate understanding of individual patients to increase the probability of successful treatment.

It is important that the term “personalized medicine (PM)” is not misunderstood. Taken literally, it could mean the development of “tailored” medicines to suit individual patients – clearly impractical. Instead, it is more appropriate to consider the application of these emerging technologies to a greater use of “personal” medical information to increase the efficiency of both diagnosis and treatment. Even considering the contribution of confounders such as environmental variables (stress, diet, and other medications) that will not allow absolute prediction, there will remain a major improvement in the probabilities of finding the right drug and dosage for a given patient. The result will be a knowledge-based reduction in the trial-and-error work of the physician, and the patient will benefit from more assured efficacy and fewer side effects.

Among the new technologies mentioned above, this paper will focus on the application of pharmacogenetics (PGx), one of the most promising biomarker technologies for addressing the challenge of variable response to medicine. The more commonly used term “pharmacogenetics” refers to the study of interindividual variations in DNA sequence related to drug response, efficacy, and toxicity (CPMP Position Paper on Terminology in Pharmacogenetics). “Pharmacogenomics” (PGm) is usually employed in a broader scope that includes genome-wide variations and potential complex interactions as well as alterations in gene expression and posttranslational modifications (proteomics) that correlate with drug response. A number of the issues associated with the evolution of PGx are applicable across a variety of other technologies; hence PGx is used as an exemplar for how the practice of medicine will be changed in future. Pharmacogenomics – and in particular, the use of gene expression patterns – is a rapidly emerging technology with a very exciting potential. The scope of this technology is being broadened by observations that lymphocyte expression profiles in easy-to-access peripheral lymphocytes appear to correlate with response in organ systems not traditionally thought to be reflected by these immune-related cells (Chon *et al*., 2004).

PGx is approaching a key milestone – it is almost 50 years since the term was first coined to capture the inheritance of altered drug metabolism (Vogel, 1959). In the intervening time, the development of the science has been impressive, but particularly so in the last few years (Roses, 2002; Goldstein *et al*., 2003): the whole area of genetics research has been transformed by technology developments underpinning the beginning of a qualitative leap in our ability to understand the basis of variable medicine response.

For much of its 50-year history, PGx has been focused on the impact of DNA variants, mainly in the drug-metabolizing system, on a medicine’s pharmacokinetic profile. *Pharmacokinetics* refers to the phenomena involved in the ushering of the active molecule into the bloodstream, its transport into the target organ, and subsequent metabolism and excretion. The impact at the target and subsequent signaling and the cascade of events that characterize the therapeutic effect are all

components of the medicine's *pharmacodynamics*. There are practical reasons why pharmacokinetics would be the first to be explored: the phenotype – concentration measures of the drug and its metabolites in blood or urine – is easily and accurately quantifiable, the number of genes involved is relatively limited, the amount of genotyping required is small (certainly by today's standards), and the impact of the genetic variation is usually high. Robust analysis of more complex phenotypes was not possible as such studies required more complex genetic analysis beyond the reach of these first technologies.

However, key technology developments have been responsible for making a wider range of efficacy and safety pharmacogenetics studies possible. First, the completion of the human genome sequence has been central to the exponential expansion of all human genetic activities, and PGx is no exception (Subramanian *et al*., 2001). Second, the advent of SNP-based high-throughput genotyping methods and platforms has fueled a dramatic increase in genotyping capacity and speed, coupled with a significant drop in costs. The increased capacity to genotype SNPs using reliable high-density maps (**http://snp.cshl.org/**) has made genome-wide scan (WGS) association studies a reality. These tools are critical in PGx, where family-based linkage analyses are both impractical and rarely possible. The most recent – and still evolving – addition to the technology armamentarium is the HapMap, which will facilitate the clustering of SNPs according to their linkage disequilibrium relationships. This will allow the selection of the most informative SNPs for genotyping, so that redundant or noninformative assays are avoided. However, such massive data-generating technologies and platforms also generate new problems in data management and massive multiple testing, requiring modified statistical analysis techniques and the application of new data mining and pattern-recognition methodologies.

2. PGx applications in enhancing the efficiency of drug discovery research and development

The last decade has witnessed astounding technological developments in many sectors of biology. However, drug discovery research has benefited from only a few novel developments despite considerable resources. In fact, the pharmaceutical industry as a whole has submitted 50% fewer new drug applications to the FDA in 2002–2003 compared to 1997–1998, while investment in biomedical research has increased almost 2.5-fold in the same period (Lesko and Woodcock, 2004). The challenge for the industry is to introduce novel strategies aimed at enhancing early stage discovery as well as the efficiency of decision making at the various stages of the pipeline (Roses, 2004).

2.1. The early stages of drug discovery: from gene to target to candidate selection

The widely held expectation, in the late 1990s, that the Human Genome Project would result in thousands of new targets led to an avalanche of ventures in

genetic research for gene and target identification for a variety of mostly common diseases, mainly in the relatively new (at the time) biotechnology sector. The majority of these initiatives were founded on a somewhat naïve extrapolation from early successes in monogenic diseases that significantly underestimated the inherent complexities of common diseases. Furthermore, the difficulties in moving from a genome sequence to disease-relevant, "tractable" (i.e., amenable to chemical screening) targets and subsequent preclinical drug discovery (Roses, 2004) were nearly universally overlooked. However, the number of known tractable targets has increased more than twofold in the last few years, from an approximate number of 500. This was mainly the result of new knowledge from the Human Genome Project, coupled with the application of novel technologies such as bioinformatics that permit more rapid exploration of gene pathways and characteristic coding regions that bear similarities to screenable gene classes (DeFife and Wong-Staal, 2002; Searls, 2003; Debouck and Metcalf, 2000). During the same period, our understanding of the molecular mechanisms underlying disease heterogeneity, gene–gene, and gene–environment interactions is steadily increasing as evidenced by the number of peer review publications in the international scientific literature, fueled by the increasing armamentarium of high-throughput genotyping, data analysis, and related technologies. Novel approaches for high-throughput experiments to discern associations between disease and disease traits with large numbers of tractable drug targets are now available (Roses, 2005).

2.2. From selecting a candidate to the clinic: the critical path of drug development

The decision as to which molecules – having been shown to have a proven effect on targets – should progress into preclinical development for subsequent use in man is a pivotal point in the pharmaceutical pipeline that has tremendous implications in financial costs, time, and effort. This "critical path" is defined as the path from candidate selection to an optimized drug through a series of (mostly animal) experiments to accumulate sufficient evidence of therapeutic effect and safety (preclinical phase). The "successful" molecule that manages to clear these hurdles is subsequently used in human (healthy and affected) volunteers in *clinical trials* designed to accurately determine its efficacy and safety.

Phase I trials comprise the first exposure in humans of a candidate medicine, and are intended to explore pharmacokinetic variables, and to ensure that there are no unacceptable safety or tolerability issues. Typical phenotypes that are studied in this phase are PK parameters such as bioavailability, clearance, and drug–drug interactions.

Phase II studies are conducted in patients aimed at evaluating a first indication of efficacy of the compound, and are sufficiently large that some safety signals may be apparent, especially "nuisance" or quality of life (QOL) side effects such as reversible changes to liver function tests. Achieving key efficacy (and safety) milestones is a critical part of the phase II studies.

Phase III studies are large trials, costing tens to hundreds of millions of dollars, providing the most convincing evidence of the efficacy and safety to support a regulatory submission. Aimed at minimizing bias and variability, they are designed as “randomized controlled trials” (RCT). The double-blind RCT model, in which neither the physician or the research subject knows what arm of the study (active drug or placebo) the patient is assigned, is the phase III “gold standard”. Owing to the size of these studies, less-common adverse events (AEs) may become apparent.

Once a medicine is registered, it can be used by a much wider population of patients. It is at this stage (*Phase IV*) that rare AEs may be identified, which could not be discovered during clinical development: even the large pivotal phase III studies lack the power to detect AEs occurring at rates less than 0.1%.

Clinical trials are, by their nature, based on a frequentist statistical model, aimed at detecting convincing evidence of efficacy and safety through the use of the drug in large numbers of patients. These numbers are needed to overcome many issues related to disease heterogeneity and the partial understanding of underlying disease mechanisms, the variability to drug response, the placebo effect, and so on. Currently, the failure rate of potential products in development is more than 80%, mainly due to poor efficacy and/or suboptimal safety. This “pipeline attrition” has a tremendous financial cost and time wastage, as the average cost to develop a market product is estimated in excess of $800 million (DiMasi *et al*., 2003). The average time to market varies between 8 and 15 years. The large-scale phase III trials consume the “lion’s share” in both time and finances and also represent approximately 50% of the overall attrition (Gilbert *et al*., 2003). There is a widespread recognition that to reduce attrition, novel approaches and tools such as PGx may enable exploration of the pathophysiological mechanisms underlying differences in drug response (Lesko *et al*., 2003). Pharmacogenetics can be applied retrospectively, looking back over the results of clinical trials, with genotypes in hand, to respond to questions and issues such as the kinetic and dynamic properties of drugs, efficacy and AEs. *Prospective PGx* would allow proactive identification of patient subgroups (e.g., disease subtypes) that would be correlated with, and be predictive of, response to a drug. If such data were available before or between Phase IIa and IIb trials, this would significantly shorten and simplify Phase III and increase their probability of success (Lesko and Woodcock, 2004). Furthermore, the ability to segment patients by therapeutic response prospectively during early Phase II development would permit the progression of multiple compounds that can treat overlapping groups of patients having the same disease label (Roses, 2004).

It is important to differentiate between safety and efficacy applications of PGx. It is now clear that the efficacy of a medicine is strongly affected by genetic variation, and is also affected by other factors such as environmental influences and placebo response. This means that efficacy PGx is unlikely to be deterministic at the individual level, but will have a critical role in significantly increasing the probability of effective response for the identified subgroups of patients. In contrast, safety PGx is focused on the individual, with specific decisions about whether to

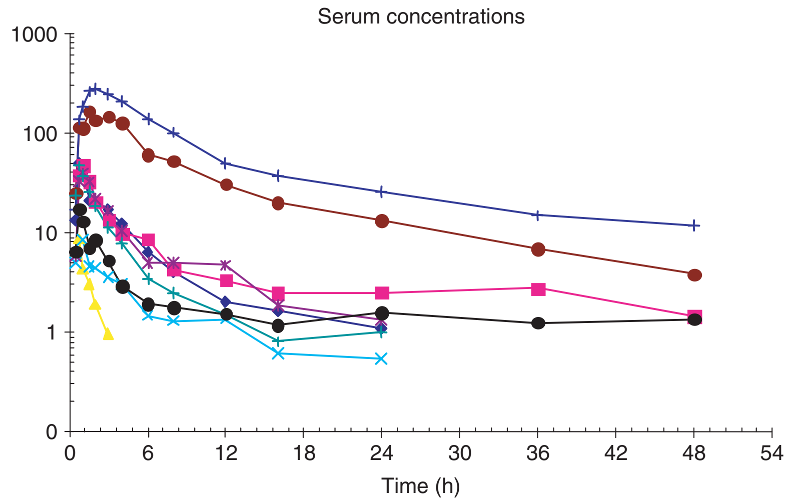

Figure 1 Typical results showing serum concentrations as a function of time for a new medicine dosed to individual human volunteers

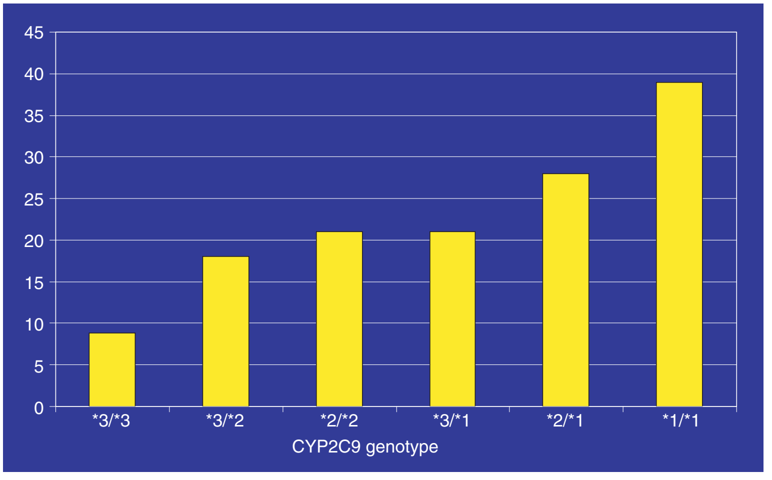
prescribe a medicine on the basis of genetic information predicting rare dangerous events and/or common adverse effects.

2.3. PGx and pharmacokinetics: aiming to predict the right dose



As mentioned earlier, the first use of PGx from the 1950s onward was to explore genetic variants that affected pharmacokinetics – especially drug metabolism (Daly, 2003). Excessive exposure in patients to medicines resulting in toxicity was the first PGx phenotype.

Figure 1 gives an example of the type of variable pharmacokinetics that can be seen in phase I studies. Each line represents the serum concentration over time for an individual subject. While most subjects cluster with similar peak concentrations and time course, there are unusually high exposures in a couple of patients, and low exposure in others. There are a number of reasons for such variability, and polymorphic variation in the drug-metabolizing enzymes is a fundamental variable to consider.

The principles underpinning such PGx experiments have remained essentially the same for many years, although current analyses are inevitably more extensive. For example, we are much more aware of the range of enzymes and transporters involved in drug disposition and clearance. Absorption and distribution (not just metabolism of drugs) are better understood and the relevant alleles are well characterized as well as their distribution in different ethnic groups (Lin *et al*., 1996; Lin *et al*., 2001). Box 1 shows an example of the quantitative impact that CYP polymorphisms can have on drug clearance. This example shows the effect of CYP2C9 variant on the maintenance dose of S-warfarin required by patients needing anticoagulation treatment.

Box 1: Effect of CYP2C9 genetic polymorphisms on warfarin maintenance dose

The chart shows the maintenance dose (in mg/week) of S-warfarin necessary to maintain adequate anticoagulant activity in patients with different CYP2C9 polymorphisms. While nongenetic factors also contribute to interindividual variability, CYP2C9 genetic polymorphisms have a significant impact on dose requirements (Reprinted from Clinical Pharmacology & Therapeutics, 72, Scordo MG *et al*., Influence of CYP2C9 and CYP2C19 genetic polymorphisms on warfarin maintenance dose and metabolic disease, 702–710. ©2002, Americal Society for Clinical Pharmacology & Therapeutics).

Such studies have established that at least 40% of drug metabolism is via polymorphic CYP450 enzymes (Ingelman-Sundberg, 2004). While these data appear straightforward, there are complexities that may impact the interpretation. For example, environmental confounders (such as smoking) can affect CYP expression and change the metabolic route. In particular, the whole area of drug–drug interactions shows the complexities that can be observed. It has been estimated that 6% of patients on two medications experience ADRs, whereas ADRs are reported by 50% of those on five medications, and nearly 100% of those on 10 medications. A major cause of these reactions is the changes produced by one drug in the metabolism of another through P450 pathways. Guzey *et al*. (2002) describe a case wherein a CYP2D6 extensive metabolizer became a phenotypical PM during treatment with the potent 2D6 inhibitor bupropion, demonstrating the complexity of assessing the exact causes of ADRs.

Despite almost 50 years of research, the application of PGx has yet to significantly impact clinical practice. For example, it is well established that CYP2D6 poor metabolizers have increased biological exposure and increased risk of AEs to a variety of commonly prescribed medicines. However, these observations have not as yet resulted in CYP2D6 testing being a routine part of the prescribing practice.

While the research literature is extensive, there is little in the way of clinical outcome studies, making it difficult for physicians to apply this technology in their prescribing decisions. Suitable prospective studies (e.g., looking at the effect of genotyping CYP2C9 on Warfarin dosing and bleeding events) are, however, now being initiated, and the results from these studies will be critical if PGx is to make significant inroads into medical practice.

Although prescribing practices are not yet significantly changed, PGx information is starting to appear in the written material (drug label) provided when the drug is dispensed. In the United States, labels for atomoxetine and 6-mercaptopurine provide the physician with information regarding metabolism by polymorphic enzymes (CYP2D6 and thiopurinemethyl transferase respectively). Physicians are alerted that tests are available to identify poor metabolizers, but are not required to carry out these tests prior to prescribing these medicines (Lesko *et al*., 2003).

The application of PGx to study pharmacokinetics is nonetheless a particular focus of attention at the moment, as drug regulatory authorities are actively exploring PGx tools to better understand drug exposure (and in particular, toxicity) and make this information available to physicians. For example, the US FDA and Japanese MHLW have already released draft guidelines relating to genomic data submission (Lesko *et al*., 2003), and the CPMP in Europe has an Expert Group on PGx to address these issues.

2.4. *Efficacy PGx – impact on attrition in development*

In addition to its direct clinical impact, variable efficacy is also an important issue for drug development. Failure to show efficacy in phase II studies is the most common reason for terminating the development of medicines. As noted above, large phase III studies to confirm safety and efficacy are very expensive, therefore if more information could be extracted from earlier, smaller Phase II studies to establish more clearly the efficacy of a candidate medicine, then valuable time and resources would be saved during Phase III. In fact, the variable efficacy of medicines, even in apparently homogeneous patient groups recruited in phase II studies, can obscure true and significant efficacy in a subset of patients, thus leading to inappropriate termination of the compound. One challenge in efficacy PGx is that in contrast to the more "single gene" character of the pharmacokinetic PGx described above, the efficacy phenotype is likely to be multigenic and thus requires more research to be fully clinically applicable.

Nonetheless, efficacy prediction is a very exciting area for PGx (see Table 1). By using genetic and/or other biomarkers to identify appropriately responding subgroups in phase II studies, compounds that are effective in patient subgroups may be further progressed, significantly increasing the delivery of new medicines to meet unmet patient needs, and increasing the productivity of pharmaceutical R&D. The critical issue is whether these phase II studies are appropriate to generate robust PGx data that can be used to impact further development of compounds. Although published data are scarce, some initial findings seem promising.

The example of Herceptin^{TM} (trastuzumab) highlights how a pharmacogenetic test can be used to progress medicines through the R&D pipeline. Overexpression

Table 1 Pharmacodynamic (drug target) polymorphisms associated with variation in medication response

Gene	Medication	Phenotype change	References
Angiotensin converting enzyme (ACE)	ACE inhibitors (imidapril, enalapril)	Blood pressure	Ohmichi *et al*. (1997)

		Side effects	Murphy *et al*. (2004) Mundo *et al*. (2001)

of the *ErbB2* gene is associated with increased tumor aggressiveness. Herceptin – a humanized monoclonal antibody against the ErbB2 receptor – is now approved for the treatment of breast cancer (Noble *et al*., 2004; Vogel and Franco, 2003). Retrospective examination of the clinical trials of Herceptin showed that a positive response was more likely in patients with tumors overexpressing ErbB2. So the measurement of ErbB2 overexpression can be used to assess whether treatment with Herceptin is appropriate. The availability of a test for a subgroup with a better probability of responding to treatment with Herceptin allowed this drug to progress through further studies to approval. The same paradigm has recently been applied to understand the response of lung cancer patients to gefitinib, where positive response is closely associated with the presence of activating mutations in the drug target (EGFR) in the tumor (Lynch *et al*., 2004). These striking results have had an immediate effect both on the way clinicians assess the role of gefitinib in cancer treatment and also on the questions that regulatory authorities require to be answered during drug development.

In another example in a recent phase II study of a GSK antiobesity compound, analysis of the whole patient groups showed efficacy less than that reported in the literature for the current "gold standard" therapies. However, PGx analysis based on candidate genes around the compound's target and presumed mechanism of action

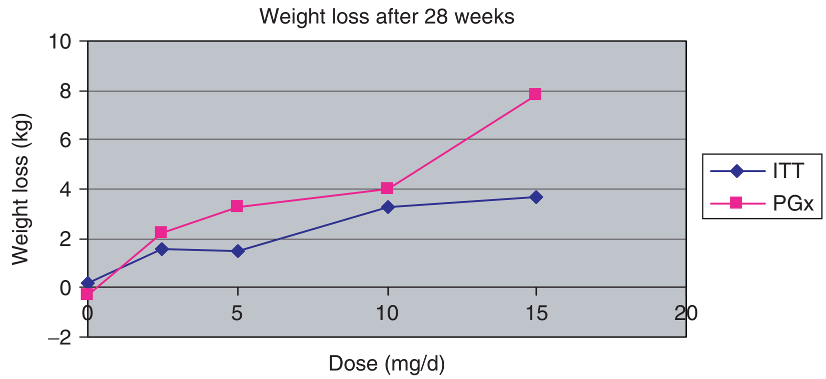

Figure 2 Dose response data showing weight loss in the whole treated population (ITT) and the subgroup identified by PGx Analysis

showed association between three genetic markers and weight loss. Using the presence of any one of these alleles to identify a subgroup, 36% of the patients could be clustered to show significantly greater weight loss. The dose response in the whole ("ITT") patient group and the PGx-defined subgroup ("PGx") is shown in Figure 2.

Analysis of a subsequent phase II study with a different antiobesity compound showed a histogram of patient numbers versus response (Figure 3). Although the average response in the placebo group was 0% change, there was considerable variation even in 8 weeks. The bulk of treated patients show some benefit, while there are some who show much greater effect ("super-responders") and also some that show very little benefit, gaining weight during the study. This visualization of the data indicates clearly the opportunities for PGx to provide insights into the variable response seen in different patient subgroups.

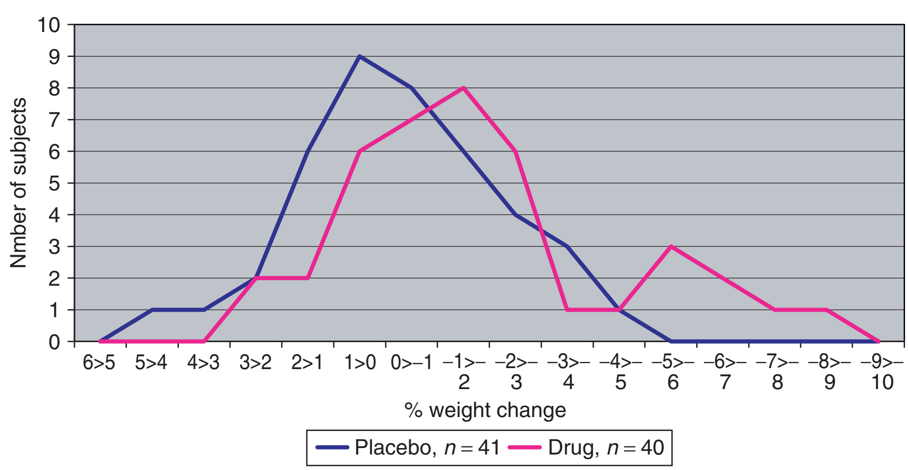

Figure 3 Variation of weight loss in placebo- and drug-treated cohorts after 8 weeks dosing

Data such as these show that phase II studies are sufficiently sized to generate PGx hypotheses that can influence subsequent development of candidate medicines. The data can be replicated and further refined in subsequent phase IIb or phase III studies.

3. PGx and safety

While there is ample evidence that medicines provide significant benefit in terms of mortality, morbidity, and cost-effectiveness, it is inevitable that ADRs are observed. Lazarou *et al*. (1998) estimated that ADRs caused approximately 106 000 deaths each year in the United States. There is increasing evidence to show that genetic variations can predispose individuals to such ADRs. For example, Rau *et al*. (2004) demonstrated that when patients were treated with antidepressants, nearly 30% of those with ADRs were CYP2D6 poor metabolizers, a group that is only 7% of Caucasians. A key objective of clinical development is to define the potential safety issues that might be associated with a new medicine, so that the risk/benefit of the medicine can be assessed.

4. Mitigating risk in development

In addition to establishing efficacy, clinical development studies must also define the safety parameters for a medicine. Although the full safety profile of a medicine cannot be established until it is in widespread use after launch, potential safety signals can be apparent in early phase II studies, and can have a significant impact on the risk for further development. For example, if reversible changes in liver function tests are seen in a small subset of patients in a phase II study, it can be difficult to assess the importance of this. Many valuable and effective medicines have a small impact on liver function, but on the other hand, a number of medicines have failed either in late development or after launch due to a subset of patients exhibiting these liver function changes, subsequently developing severe liver failure. If high-risk patients could be identified with inexpensive genetic screening before starting the drug, the overall safety would increase considerably, and abrupt termination of a drug that has progressed to late stages could be avoided.

PGx is expected to greatly illuminate the basis of liver function changes in drug development. In recent clinical studies on Tranilast (a product intended to reduce restenosis after coronary angioplasty), some 8% of individuals showed an increase in unconjugated bilirubin, which resolved on termination of drug treatment. This phenotype showed some similarity to Gilbert's syndrome, a well-recognized condition characterized by episodic increases in unconjugated bilirubin but not associated with any long-term impact on liver functioning.

Genetic analysis of Gilbert's syndrome patients has established a strong genetic susceptibility marker in the promoter of the gene *UGT-1A*, where a variable TA repeat is located. "Wild-type" activity is associated with six copies of the TA repeat, whereas seven copies of the TA repeat is associated with reduced expression of UGT-1A, and increased propensity to Gilbert's syndrome.

Figure 4 shows the result of an association analysis studying bilirubin levels as phenotype in the Tranilast-treated subjects. There is a highly significant association between the TA repeat genotype and the likelihood of developing raised bilirubin after treatment with Tranilast. This strongly supports the hypothesis that the observed hyperbilirubinemia can be described as a Tranilast-induced Gilbert's syndrome.

As the elevated bilirubin could be ascribed to a well-known, benign syndrome, with no evidence for progression to serious liver disease, the likelihood that this safety signal with Tranilast could lead to serious liver complications was significantly reduced. A similar clinical observation (i.e., elevated unconjugated bilirubin in a subset of patients) has also been seen in studies with atazanavir (BMS) and the phenotype was in turn strongly associated with the UGT-1A promoter polymorphism, suggesting a similar basis for the clinical observation.

In summary, these results not only show how PGx can provide insights into safety signals apparent at phase II but also underscore the role of PGx in providing information to help R&D decision making. This use of PGx data will be critical in facilitating the development of new medicines by pharmaceutical companies.

As significant numbers of samples were available from phase III studies (where elevated bilirubin was also seen in a small percentage of subjects), this data set has provided significant information on the power of genetic datasets to identify PGx signals and to explore other aspects of experimental design. For example, greater power can be obtained by increasing the number of controls. Perhaps more surprising is that epidemiological controls from an unrelated population can be as effective as the matched controls from the phase III study sites. This is particularly

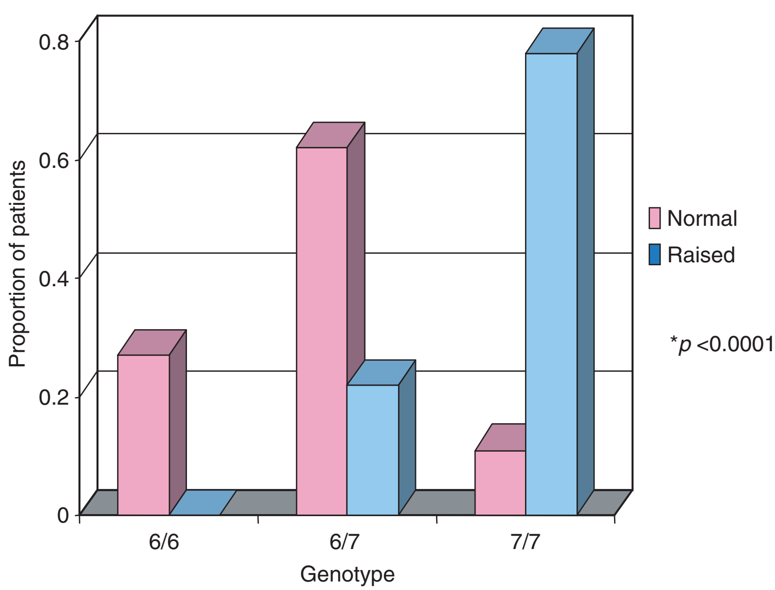

Figure 4 Effect of TA repeat number in the UGT-1A1 promoter region on the proportion of patients with normal or raised bilirubin levels after treatment with tranilast

Table 2 Impact of varying number of cases of elevated bilirubin after tranilast treatment on statistical significance of association between SNPs in the promoter region of UGT-1A1

Approximate number of cases	Approximate number of random controls	SNP poly ID			
		4082379	3729885	3730948	3737550
10	3000	0.10392	0.01542	0.04623	0.00644
20	3000	0.00143	4.37E-6	0.00014	9.96E-8
30	3000	3.93E-6	2.91E-7	4.14E-5	5.59E-9
50	3000	8.69E-8	7.39E-08	2.47E-5	1.32E-10
100	3000	1.80E-10	3.87E-13	1.24E-8	9.12E-16
120	3000	9.21E-11	1.91E-15	3.26E-10	2.21E-18
146	3000	2.56E-13	2.70E-18	6.10E-13	4.53E-23

true if genomic control measurements (Devlin and Roeder, 1999; Pritchard and Rosenberg, 1999) are performed to document and correct for stratification in the samples. In addition, it is clear that in this case, as few as 10 cases of hyperbilirubinemia would be needed to establish a positive association with the UGT-1A promoter polymorphism, using a sufficient number of controls – findings that will help immensely in the design of future PGx experiments (Danoff *et al*., 2004). Table 2 shows the PGx association p-value for increasing number of cases using 3000 population controls. Significance can be seen even with 10 cases, and with 20 cases the finding would be significant even when correcting for multiple testing in a broader candidate gene study.

5. PGx and adverse events – postlaunch

Much PGx discussion has centered on the contribution of PGx to understanding rare AEs. Because there are fewer cases of such AEs, it is unlikely that the approaches described above, that is, the selection of cases from a clinical trial population using the remainder of the cohort as controls, is viable; sufficient cases may only be available once a medicine is registered and more widely available. In this case, retrospective collection of both cases and controls may be required, and various approaches are being investigated to expedite efficient collection of such cases and controls to allow PGx experimentation.

The studies on hypersensitivity reaction (HSR) to abacavir (ABC) have been used as proof of concept on the feasibility of retrospective case/control approaches wherein the number of cases (rare AEs) is small, and genome-wide association is applied. HSR affects ∼4% of subjects with HIV who are treated with ABC, and while the clinical sequelae can be serious, tight clinical management of HIV subjects has prevented significant mortality due to this AE. DNA was collected from subjects reporting HSR after exposure to ABC, and from matched controls with no HSR symptoms after ABC treatment. Genotyping included both candidate gene and genome-wide SNP association approaches.

Candidate gene analysis identified a site in the human leukocyte antigen (HLA) of chromosome 6 with strong association with HSR (Hetherington *et al*., 2002). This finding has been confirmed by at least two other laboratories. Work to analyze

the genome-wide association data is being finalized and will be reported soon. The association between markers in the HLA region is strong in Caucasians, weaker in Hispanics, and cannot be detected in Blacks.

Studies have also been reported on genetic associations with Stevens Johnson Syndrome (SJS), a rare, serious cutaneous reaction to some medicines (Chung *et al*., 2004). The finding that the marker HLA-B*1502 is strongly associated with carbamazepine-induced SJS is another indication that this technology can provide significant new insights into the basis of such rare AEs.

There are now an increasing number of studies – HSR to ABC, SJS in response to carbamazepine, hyperbilirubinemia in response to Tranilast – that have established PGx associations with only a few tens of AE cases, possibly an indication of the genetics "truism" that the rarer an event, the more likely there is to be a strong genetic component.

These studies have led to several significant learnings:

- Retrospective case/control PGx studies on AEs are certainly feasible, although particular care must be taken in defining the phenotype with great accuracy. Phenotype collection is arguably the most critical part of any genetics study, and it may be difficult to collect sufficient detail for AEs observed away from the controlled, monitored clinical trial environment.
- Findings in one ethnic group are not necessarily applicable to other ethnic groups. It is unclear at this stage whether this is due to different genetic architecture at the same locus, or different aetiology of the AE, but resolution of this issue is important for moving forward.

Taking the physicians' point of view, each day they face the same dilemma over and over again: what is the right drug and the right starting dose for this patient? Medical training and clinical experience has taught the physician some of the considerations important in this decision, including the patient's age, sex, race, compliance, and level of anxiety. However, as every physician knows, prescribing medications is a combination of the clinical arts and inexact sciences, leading to an often bewildering variety of outcomes across a group of patients. At times, the physician may be overwhelmed by the complexity and unpredictability of a given patient's response to a medication. The way out of this trial and error prescribing lies in the increased data collection and sophistication of our knowledge regarding the causes of variable response and side effects. A cultural shift will need to occur in the way physicians approach prescribing drugs. In the coming years, automated and progressively more inexpensive genotyping will provide the physician with increasing amounts of information regarding how a given patient will react to a particular medication. However, most of this information will arrive in their hands as probabilities, particularly in predictions of efficacy, because of the interactive complexities of multiple genetic and environmental determinants. Medical schools may need to develop new curriculum in the area of pharmacogenetics, with input not only from the mainstream areas of pharmacology and genetics, but also from statistics, epidemiology, and genetic counseling, perhaps building on the experience of other parts of medicine – such as CV risk assessment – where estimation and communication of risk has been central for a number of years.

The examples given above are a clear indication of the potential of PGx to have a major impact on the development of new medicines as well as their use by prescribing physicians. Once the technology is mature, integrated into drug development processes and incorporated into clinical practice, the expectation is that:

- the delivery of new medicines through pharmaceutical R&D will increase, both through a greater understanding of nonserious safety issues, and progressing compounds effective in a genetically defined patient group;
- the clinical effectiveness of these medicines will be enhanced through an understanding of the patient subgroups and their different responses;
- the mortality and morbidity associated with AEs will be reduced as high-risk individuals can be directed toward alternative therapies.

The transformation of medical practice resulting from these developments will make significant difference to the lives of patients, as well as making the use of resources more rational, both by health care providers and pharmaceutical companies.

The development of PGx and other technologies applicable to "personalization" of medicines is proceeding at such a pace that it is not a matter of "if" these technologies impact medicine prescribing, but "when" – and to what extent. It is critical that the development of this approach is not unnecessarily hampered and that the balance between scientific progress and safeguarding patient rights is appropriate. Potential threats to the development of this technology include not only the natural resistance to new medical methods but also "genetic exceptionalism" – the view that genetic information is inherently more sensitive than other biomarkers and hence requires extreme regulation over its generation and use. This view is most common in people who do not understand genetics well and thus develop a fear of the unknown or whose views are dominated by the determinism that characterizes the single gene disorders. Despite these obstacles, the emerging data in support of PGx are compelling and warrant time and effort to develop their utility and to bring these applications to clinical fruition.

Specialist Review

SNPs and human history

Jeffrey D. Wall

The University of Southern California, Los Angeles, CA, USA

1. Introduction

Both physical anthropologists and evolutionary biologists have long been fascinated by the evolution of our own species. Researchers have tended to focus on either the demographic history, such as population structure, population expansions/bottlenecks, and the colonization of new islands/continents, or the selective history such as the genetic basis of human-specific adaptations (e.g., language) or the evolution of population-specific local adaptations (e.g., lactose tolerance). Single-nucleotide polymorphisms (SNPs) are informative about these questions, especially SNPs that are obtained from resequencing studies. By carefully analyzing patterns of SNP variation within and between populations, we can learn a lot about human evolution.

Early studies of human SNP variation centered around mitochondrial DNA (mtDNA) and the nonrecombining portion of the Y chromosome (e.g., Vigilant *et al*., 1991; Hammer, 1995). These two regions are easier to study because of their uniparental mode of inheritance, but they represent a minute fraction of the total information contained in our genomes. With the development of new SNP typing and sequencing technology, we have witnessed an explosion of SNP data over the last several years. Researchers have gathered SNP data from markers throughout the genome (e.g., Akey *et al*., 2002; Gabriel *et al*., 2002; IHC, 2003) as well as resequencing data from genes (Reich *et al*., 2001; Stephens *et al*., 2001; Carlson *et al*., 2003), intergenic regions (Frisse *et al*., 2001), and even whole chromosomes (Patil *et al*., 2001). These and other studies have revealed three major patterns: (1) overall levels of variation are quite low relative to other great ape species, (2) there is a tremendous amount of variability across regions in overall patterns of SNP variation, including differences in the level of nucleotide diversity, the strength of linkage disequilibrium, and the allele frequencies of SNPs, and (3) there are systematic differences in levels and patterns of polymorphism among human populations. The connections between these observations and explicit models of human evolution are not always clear.

2. Small effective population size

Studies of human variation have consistently found low levels of polymorphism, corresponding to a long-term "effective population size" (N_e) of roughly 10 000–

15 000 (Ptak *et al*., 2004; Yu *et al*., 2004). In other words, levels of human genetic variation are equal to what would be expected in a selectively neutral, random-mating population of 10 000–15 000 individuals. On the surface, this observation is surprising, since hominins have occupied much of the Old World for more than 1 million years. In contrast, great ape species have had much smaller ranges; yet, three out of four species (all but the bonobo) have effective population sizes substantially larger than the human effective population size (Kaessmann *et al*., 2001; Yu *et al*., 2004). The small human N_e has been taken as evidence against the multiregional model of modern human origins (Harpending *et al*., 1998). The multiregional model, which posits that modern humans evolved simultaneously on multiple continents, generally assumes that the fossil hominins that cover much of Europe, Asia, and Africa were our direct ancestors (Wolpoff *et al*., 1984). How could such a widely dispersed successful species have such a small N_e? One possible explanation is that many of the humanlike fossils that have been discovered (e.g., the Neanderthals in Europe) are not our direct ancestors. This is the main premise of the Recent African Origin model, which posits that modern humans evolved in a small area of Africa roughly 130 000–200 000 years ago (Stringer and Andrews, 1988). Under this model, modern humans subsequently expanded and replaced all other hominine populations. However, it is not clear whether $N_e = 10\,000–15\,000$ is really incompatible with long-term continuous occupation of the Old World as census sizes can be substantially larger than effective population sizes. In fact, recent studies of historical human populations have suggested that census sizes can be hundreds of times larger than effective population sizes (e.g., Helgason *et al*., 2003).

3. Heterogeneity across regions

As more and more data have become available, it has become apparent that patterns of SNP variation are not uniform across the genome. For example, while many regions have an excess of low-frequency variants, others do not. Some regions show extensive linkage disequilibrium between markers that are hundreds of kilobases apart, while other regions have a complete breakdown of LD over just a few kilobases. Some regions show extensive differentiation between different populations, while others show no differences across populations. Much of this heterogeneity is due to the inherent stochasticity of the evolutionary process, but part is attributable to variation in the underlying biological parameters. Both the neutral mutation rate and the recombination rate are not constant across the genome; the recombination rate, for example, can vary by several orders of magnitude over fine scales (Crawford *et al*., 2004; McVean *et al*., 2004). Natural selection can also lead to unusual patterns of variation; the *FOXP2* gene shows an excess of rare alleles due to a recent selective sweep (Enard *et al*., 2002), while other genes show increased differentiation due to adaptation to specific environments (Hamblin *et al*., 2002).

This heterogeneity across regions makes the interpretation of the patterns of variation at any particular locus extremely challenging. For example, an excess of rare polymorphisms at a locus may be evidence for recent population growth (Wall and

Przeworski, 2000), or the signature of recent adaptive evolution (Braverman *et al*., 1995), or just the chance effects of genetic drift. Without additional information, it may be impossible to distinguish among these three possibilities. It is for this reason that studies of a single linkage group, such as the plethora of evolutionary studies on mitochondrial SNPs, are inherently limited.

The effects of natural selection on patterns of variation tend to be localized to small regions (i.e., sites linked to those under selection) owing to recombination, while the effects of demography (e.g., subdivision, admixture, changes in population size, etc.) are visible throughout the whole genome. Thus, to adequately address questions of demography, it is necessary to gather polymorphism data from many evolutionarily independent regions, preferably noncoding regions that are less likely to have been affected by natural selection. Once enough data from putatively neutral loci have been gathered, one can use them as a baseline when looking for loci that have recently been affected by natural selection. Selected loci may show up as outliers in the empirical distribution of some summary of the data (e.g., Hudson *et al*., 1987; Akey *et al*., 2002).

4. Differences across populations

Despite the heterogeneity across regions in patterns of SNP variation, there are systematic differences in the patterns of variation of different human populations. On the basis of SNP data from hundreds of loci, we know that (many but perhaps not all) sub-Saharan African and African-American populations have more genetic variation (Frisse *et al*., 2001; Carlson *et al*., 2003), harbor more rare alleles (Ptak and Przeworski, 2002), and have lower levels of linkage disequilibrium (Frisse *et al*., 2001; Reich *et al*., 2001; Wall and Pritchard, 2003) than other populations. These systematic differences suggest differences in the underlying histories of sub-Saharan African (and African-American) versus other populations. We note in passing that these observations are supported by other marker systems such as microsatellites (e.g., Bowcock *et al*., 1994).

Some have claimed that all non-African populations have undergone a recent population bottleneck (Tishkoff *et al*., 1996; Reich *et al*., 2001), as predicted by the Recent African Origin model. Indeed, recent bottlenecks lead to reduced variation, increased linkage disequilibrium and a shift toward more common alleles (e.g., Reich *et al*., 2001), so some form of bottleneck is a likely and appealing explanation. There still remain some unresolved questions though. Little work has been done to estimate the timing and strength of a putative bottleneck, to ascertain whether all non-African populations show evidence of a recent bottleneck and all sub-Saharan African populations (and populations with a substantial sub-Saharan African component) do not show evidence of a bottleneck, or to rule out other possible demographic explanations (e.g., Relethford and Jorde, 1999).

5. Models and data

What do the patterns of SNP variation tell us about the various models of human evolution? It has been difficult to come to definitive conclusions (e.g., on the validity of the Recent African Origin or multiregional models) for several reasons. First

of all, anthropological genetics models are verbal models that are not necessarily easily defined or quantified. The multiregional model is particularly vague, with a definition that seems to have shifted over the years (Relethford, 2001). Even the simpler Recent African Origin model is rarely made specific. Only explicitly formulated models can be rigorously tested using genetic data.

Take for example the debate on modern human origins. In a genetic sense, we can ask what contribution various "archaic" human populations (e.g., the Neanderthals in Europe or *Homo erectus* in East Asia) have made to the contemporary human gene pool. The multiregional model predicts that this contribution would be substantial, while the Recent African Origin model predicts that this contribution is negligible. Other models predict intermediate contributions of archaic populations to the modern gene pool (e.g., Bräuer, 1984). When the debate is phrased in this way, we have a well-defined genetic question and a set of mutually exclusive predictions that might allow us to discriminate between models. This well-defined question is not particularly easy to answer, because the predictions of the different models differ only slightly and because the theoretical tools for distinguishing between these small differences have not yet been developed. There is hope, though, that we will be able to solve this question in the next few years.

Given only contemporary human sequences, it is difficult to say much about admixture levels 30 000–100 000 years ago since genetic drift in the intervening years would have mostly obscured the pattern of admixture. What we would really like is to have a direct comparison of DNA sequences from both archaic and modern populations. This is technically challenging but in a recent breakthrough, researchers have managed to sequence fragments of Neanderthal mtDNA from fossil bones (e.g., Krings *et al*., 1997; Serre *et al*., 2004). All of the Neanderthal mtDNA sequences were found to be highly diverged from contemporary human mtDNA sequences, implying that Neanderthals made no contribution to the contemporary mtDNA gene pool. However, we still do not know whether Neanderthals made any contribution to the nuclear gene pool. Recent studies suggest that even if Neanderthal genes make up as much as 25% of the current gene pool, Neanderthal mtDNA could still have been lost from the current mtDNA gene pool by chance (Nordborg, 1998; Serre *et al*., 2004).

It is unlikely that any appreciable amount of nuclear DNA sequence will be recovered from Neanderthal remains, so further progress will probably come from the analysis of contemporary human DNA. Given a simple admixture model and polymorphism data from a sufficiently large number of loci, it should be possible to estimate admixture proportions (Wall, 2000). The question remains open in part because the requisite experimental data have not yet been gathered.

6. Future directions: data

Despite the presence of a huge amount of SNP data gathered by the genetic mapping community, much of these data are not directly useful for evolutionary studies. Genotype data on SNPs from the public databases (e.g., Gabriel *et al*., 2002; IHC, 2003) do not provide information on the levels of variation and are difficult to analyze because of ascertainment bias. Public database SNPs are

not a random collection of SNPs. Most were ascertained by sequencing a small number of (predominantly European) reference chromosomes. SNPs discovered in this manner are often typed in a larger group of individuals, and the patterns of linkage disequilibrium and population frequencies in such data are affected by the process by which the SNPs were originally identified (Nielsen and Signorovitch, 2003). While, in principle, analytical methods can correct for ascertainment bias, this presupposes that the process by which SNPs were first ascertained is completely known; often this is not the case. In fact, even the number of reference chromosomes is often unknown! So, it is far simpler for analysis and interpretation to gather resequencing data.

Ideal data for studies of human population history might be resequencing data from many independent regions in a worldwide sample of humans. To reduce the confounding effects of natural selection, the regions should be single-copy noncoding regions in areas of low gene density and high recombination. To help distinguish various demographic effects (e.g., population structure and population growth), it is best to collect data with a consistent sampling scheme and to have a sizable sample size from each population studied (Ptak and Przeworski, 2002).

While there are some large-scale resequencing projects in progress (e.g., Frisse *et al*., 2001, or the sequencing of ENCODE regions for the HapMap project), these projects have generally considered a limited sample of human populations: a European population, an East Asian population, and a West African population. It is still an open question whether such limited sampling adequately represents the full spectrum of human SNP diversity. If recent studies of microsatellite variability (e.g., Rosenberg *et al*., 2002) are any indication, the answer is no. Our understanding of human demographic history will be richer if we gather sequence data from multiple sub-Saharan African populations, and from populations from the Middle East, South Asia, Melanesia, and the Americas.

For questions regarding selective history, many of the same suggestions apply. Resequencing data from a worldwide sample of humans provide the ideal data for understanding the effects of natural selection on the human genome. The only difference would be a focus on functional regions (e.g., genes or promoter regions) rather than on putatively nonfunctional ones. Ideally, all population genetic studies (whether the focus were on selection or demography) would use a common set of DNA samples. That way it would be easier for the studies of natural selection to control for the confounding effects of demography. The Human Genome Diversity Project cell line panel housed at the Foundation Jean Dausset (CEPH) in Paris is one obvious possibility (Cann *et al*., 2002).

7. Future directions: models

From the modeling side, more effort needs to be spent formulating specific models, estimating parameters, and developing methodology for discriminating between models. Most models are based on the coalescent (Hudson, 1990), which provides a simple yet powerful method for simulating population histories. So far, methods have been developed for looking at population growth (e.g., Pluzhnikov *et al*., 2002), population structure (e.g., Hey *et al*., 2004), ancient admixture (Wall, 2000),

recent natural selection (e.g., Przeworski, 2003), and variation in recombination rates (Crawford *et al*., 2004; McVean *et al*., 2004). In reality, these models are too simple. An accurate representation of human demography requires both population structure and changes in population size, while studies of natural selection cannot ignore the underlying demography. The challenge lies in formulating models that are detailed enough to capture the fundamental biological complexity but simple enough to be computationally tractable. These methods will need to be tailored toward handling the flood of SNP data that are already becoming available.

8. Conclusions

The field of human evolutionary genetics is in a state of flux. The answers to crucial questions that have been open for decades seem to be tantalizingly close; in most cases, we have partial answers but no definitive conclusions. Given the recent advances in sequencing technology, there will soon be a flood of sequencing data gathered specifically to answer human evolutionary questions. The methods for analyzing these data will soon follow. This is an exciting time – one where we will reach the limit of what we can learn about our own history from our own DNA sequences.

Short Specialist Review

Evolutionary modeling in haplotype analysis

Peter Donnelly
University of Oxford, Oxford, UK

Continuing advances in high-throughput genotyping technologies mean that data sets documenting genetic variation at very closely spaced markers are becoming routine, even on genomic scales. The International Haplotype Map project (HapMap), which by mid-2005 will provide genotypes at a density of more than 1 SNP marker per kilobase for 270 individuals from four population samples, is just one public resource (**www.hapmap.org**). With the advent of genome-wide association studies for complex human diseases, genetic variation data at hundreds of thousands of markers will be combined with phenotype information from disease cases and from control individuals.

The patterns observed in such variation data result from a complex interaction of different effects: the genetic forces of mutation, recombination, and possibly natural selection; the demographic history of the populations carrying ancestors of the sampled chromosomes; and a whole series of chance events. In addition, the genomes of individuals affected by a disease with a genetic component are more likely than those of control individuals to carry the genetic mutations that increase the relative risk of suffering from the disease. In principle, then, variation data is informative about each of these effects, and different studies may focus on different aspects. For example, several studies have recently utilized variation data to elucidate the fine-scale structure of recombination rate variation in the human genome (e.g., McVean *et al*., 2004; Crawford *et al*., 2004), to detect regions possibly under natural selection (Sabeti *et al*., 2002), and to study the histories of human populations (e.g., Reich *et al*., 2002).

In human disease studies and for other many other purposes, the evolutionary history of the sample and the genetic forces that shape it are not the primary interest. Nonetheless, even in these contexts, it can be helpful to bear in mind these evolutionary effects. At an informal level, they allow useful insights into the structure of the data. Of more practical relevance, it is becoming clear that analytical methods that directly or indirectly model evolutionary history are often more powerful than existing approaches, even for questions not directly related to that history. In summary, if we want to use genetic variation data from population samples to learn about evolutionary forces (recombination rates, selective pressures), we must use some kind of model that relates the forces of interest to aspects of the data. But even if we want to use the data for other purposes,

including disease mapping, we will often be able to get more information from the data if we exploit knowledge of the evolutionary forces that shaped it.

We illustrate by briefly considering one particular problem: inference of haplotype phase from genotype data. Most genotyping methods give the diploid genotypes at each of the markers tested independently. Of course, in any individual, variant alleles at nearby markers are arranged along the individual's two chromosomes. If we were able to read each chromosome separately, we would learn the two *haplotypes* carried by that individual, that is, the sequence of variants along each of the two chromosomes. In practice, genotyping (and DNA sequencing) methods routinely provide unphased information: we learn which variants the individual has at each marker, but not the "joined up" information about which variant at one marker is on the same chromosome as the variants at a nearby marker. For many purposes, it is the haplotypes themselves that are of primary interest as these are the natural units by which genetic information is passed from generation to generation. There are experimental methods for directly determining haplotype phase, and much of the phase information can be recovered if parents or offspring are genotyped in addition to the individuals of primary interest. But these approaches involve considerable additional cost.

An alternative is to use statistical methods to infer, or estimate, phase from the original genotype data, and it turns out that the best such statistical methods perform remarkably well. This may initially appear paradoxical. Where is the information coming from to learn about phase? Evolutionary models provide the insights. First, although there is an enormous number (2^{L-1} for L SNP loci) of different possible haplotypes, it turns out that models predict that there will be relatively few different haplotypes actually present in a population sample, since the haplotypes present share a common ancestor relatively recently (e.g., Donnelly and Tavaré, 1995). Were it not for mutation and recombination, all sampled haplotypes would be the same as their most recent common ancestor. Mutation and recombination do create new haplotypes, but our understanding of evolutionary models shows that there is just not enough time to create too many, and certainly nowhere near the number of all possible haplotypes. Empirical studies in humans and other species have verified this theoretical prediction. Methods for inferring phase from genotype data directly or indirectly take advantage of this observation, in effect looking for collections of haplotypes that are consistent with the genotype data in which a small number of haplotypes recur in many different individuals. (Some approaches explicitly try to minimize the number of observed haplotypes, although this is a hard computational problem for large data sets. In other approaches, including, for example, the use of maximum likelihood via the EM algorithm, it happens indirectly.)

Phase inference is thus a simple example where an understanding of evolutionary models is helpful. In fact, there is another lesson from that example. The most accurate phase inference methods such as PHASE (Stephens *et al*., 2001; Stephens and Donnelly, 2003) do better than other approaches because they exploit this understanding more deeply. Not only will there be relatively few haplotypes in a sample, but exactly because they share a recent common ancestor, the haplotypes that do occur will be relatively similar. PHASE embodies the intuition that when we see a haplotype that has not been previously observed, it is likely to be closely

related to haplotypes already seen in the sample, in the sense that it can be created from them by a small number of mutation and recombination events.

What do the evolutionary models used in these applications look like? There is a natural family of models based around the *coalescent*. In its simplest form, the coalescent is a probabilistic description of the ancestral trees that link sampled haplotypes back to their most recent common ancestor, in a large randomly mating population of constant size. There are extensions to this basic model to incorporate much more complicated demographic scenarios, the effects of recombination, and of natural selection (see Donnelly and Tavaré, 1995, or Nordborg, 2001, and references therein). Empirical data documenting genetic variation has a complicated correlation structure: the variants carried on a particular chromosome are correlated as one moves along the chromosome (this is known as linkage disequilibrium). In addition, these are correlated across chromosomes because of the shared evolutionary ancestry. When it comes to interpreting genetic variation data, we can think of the coalescent as providing a model for the randomness generating the data, and in particular for the correlations in the data.

Although coalescent models are well understood, and very useful for simulating data under various scenarios, their use in empirical data analysis is not without its challenges. In effect, the complications of the model make its direct use difficult. There has been considerable recent research activity in this area into approaches that try to utilize all of the information in the data (e.g., Stephens, 2001; Fearnhead and Donnelly, 2001, and references therein). But these are extremely computationally intensive, and currently impracticable for all but small data sets. A common alternative approach has been to summarize the information in the data, and to base inference on these summaries. More recently, various authors have developed approximations to the full coalescent model. The challenge in this approach is to retain enough of the features of the ordinary coalescent to keep much of the power of coalescent-based approaches, yet to simplify things sufficiently so as to make inference practicable for the sizes of data set currently being generated.

One interesting application of this last strategy has been in methods for studying fine-scale variation in recombination rates, and in detecting recombination hotspots, from population data. It has long been known from pedigree studies that recombination rates vary over chromosomal scales in the human genome. However, these approaches do not have the resolution to estimate recombination rates over kilobase scales (since recombination occurs on average once per 100 Mb in human meiosis). More recently, sperm studies have characterized recombination hotspots (in males) as regions of 1–2 kb in which recombination rates are elevated considerably compared to the background rate. Sperm studies are restricted to male recombination, and are not practicable over genomic scales. Population variation data is shaped by historical recombination events, among many other things, and so in principle carries information about recombination rates, provided these can be teased out from the other effects. Several statistical methods have been developed, each employing a different approximation to the coalescent model (McVean *et al*., 2004; Crawford *et al*., 2004; Fearnhead *et al*., 2004). These methods have revealed extensive fine-scale variation in historical recombination rates, and have shown that recombination hotspots are a ubiquitous and common feature of the human genome, providing valuable insights not available from any other approach. (There

is growing evidence that this fine-scale recombination landscape is evolving very quickly. If this is the case, population-based methods, which estimate sex-averaged recombination rates averaged over long periods of time, will be estimating fundamentally different quantities from sperm studies, which estimate current male recombination rates in the individuals studied. For many purposes, including disease mapping and most population genetics applications, it is the historical rates that are of primary interest. In understanding the molecular drivers of recombination, it is the current rates that are of interest.)

The coalescent models that underlie current methods make very simple assumptions about population demography, and concerns are often expressed about how unrealistic these are for actual human population histories. Given this obvious mismatch between the modeling assumptions and reality, how can coalescent approaches be useful at all? Statisticians have an aphorism that "all models are false, but some are useful". One should not ask whether a model captures all the relevant features of the real world. What matters is whether the model captures *enough* important features to make it useful, and there is now substantial evidence that coalescent approaches do indeed capture enough of the structure of empirical data to make them extremely valuable. The two applications we have outlined above, namely, phase inference and detection of recombination hotspots, are good examples of this.

In summary, an understanding of the evolutionary processes that lead to the empirical data being generated in many studies can be extremely helpful in guiding its interpretation. More quantitatively, the explicit use of evolutionary models, in particular, the coalescent and approximations to it, has been shown to lead to statistical approaches that are often much more powerful than existing approaches. This may not be surprising for studies that focus directly on the effects shaping the data. But it remains true even when these are not of primary interest. Phase inference is one example. Another context of considerable current interest is disease mapping. Coalescent methods have been successfully developed for fine mapping. It seems likely that they will soon be available, and offer improvements in power, for analyses of genome-wide association studies, or in the choice of tagging SNPs.

Short Specialist Review

Creating LD maps of the genome

Andrew Collins and Sarah Ennis
University of Southampton, Southampton, UK

1. Linkage and linkage disequilibrium maps

Linkage mapping has been tremendously successful in the localization of many genes involved in severe genetic disorders (major genes). The localization of a disease-influencing polymorphism is achieved by analyzing families to track the coinheritance of disease phenotype and marker polymorphisms. This enables polymorphisms that are linked (found on the same familial haplotype as the disease gene) to be identified. Once linkage is established, various approaches are employed to fine map the candidate gene region (which may span several megabases) until the causal gene is itself identified. Through this process, known as "positional cloning", disease genes are localized without having prior knowledge of their function. Linkage disequilibrium mapping exploits allelic association in a similar way but has the outstanding advantage of significantly higher resolution.

Recombination events do not occur uniformly across the chromosome, which results in some chromosome regions having intense recombination (hot spots) and other regions having low recombination (cold spots). In contrast to physical maps, which give locations for markers in megabases (Mb) or kilobases (kb), genetic linkage maps are expressed in centimorgans (cM). Although a good rule of thumb is that 1 cM is equal to 1 Mb, patterns of recombination are such that recombination hot spots show a much higher cM/Mb ratio and recombination cold spots show the converse. Understanding the variation in recombination rates is vital for disease mapping. Making the assumption that a small genetic distance implies close proximity of a disease gene can be very misleading. In the Hemochromatosis gene region, the cM/Mb ratio is only 0.16, indicating a recombination cold part of the genome. Positional cloning of this gene was delayed because applying the 1 cM$\sim$1 Mb rule suggested that the disease gene was within $\sim$750 kb of a marker, whereas in actual fact, the gene was 4.6 Mb away (Lonjou *et al*., 1998).

Although linkage maps are essential for multipoint mapping of major genes, they are of relatively low resolution because rather small numbers of meioses are accumulated in the families studied. A linkage disequilibrium map, however, reflects the historical accumulation of recombination events over many generations. LD maps therefore offer much higher resolution, suitable for mapping genes for common conditions, such as asthma and heart disease. The relationship between LD patterns and recombination is not a simple one, however, because of the confounding effects of evolutionary processes such as drift, mutation, and selection.

2. Linkage disequilibrium maps – theory and application

The pattern of LD across genomic regions shows domains or blocks of elevated LD interrupted by discrete regions of LD breakdown. These blocks correspond to extended regions of diminished haplotype diversity (Daly *et al*., 2001), while the areas of LD breakdown are coincident with narrow zones of elevated recombination as revealed by direct sperm-typing analysis (Jeffreys *et al*., 2001). To represent these variations, LD maps track fluctuating levels of LD across a genomic segment and represent these data in an additive (or metric) manner when plotted against physical distance in kilobases. An approach to constructing such maps adopts the rho (ρ) metric for association (Collins *et al*., 1999), between pairs of single nucleotide polymorphisms (SNPs), and models the decline of association with distance by the "Malecot" equation: $\rho = \mathrm{L} + (1 - \mathrm{M})\mathrm{Me}^{-\varepsilon \mathrm{d}}$. This equation has the same form as that described by Malecot for isolation by distance, but has different parameters (Morton, 2002). The population genetics theory, which provides the justification for the use of this equation to describe LD, is given by Morton *et al*. (2001). Each of the parameters has a biological interpretation, which allows comparisons of populations or chromosome regions; L accounts for the bias introduced by residual association at large distance; M reflects association at zero distance with values close to one indicating monophyletic origin and values less than one indicating polyphyletic inheritance; ε reflects the exponential decline of association with distance, dominated by recombination (Collins and Morton, 1998). The inverse of ε known as the "swept radius" is a more intuitive interpretation of ε as the distance at which LD has declined to approximately one-third of its magnitude at zero distance. Optimality of the ρ metric for pairwise LD has been demonstrated (Morton *et al*., 2001). The ρ metric was shown to be the most robust to variations in allele frequency when compared with a wide range of alternative pairwise measures of LD. Estimates are also consistent, whether calculated using phase-unknown genotypes (diplotypes) or from haplotype data.

Maniatis *et al*. (2002) applied the ρ metric to create LD maps from pairwise association data by estimating ε for each interval between adjacent SNPs in a high-density map. This is achieved by fitting the Malecot model for all informative pairs that contain the interval. The model weights pairwise data by a function of the distance between each pair so that pairs of SNPs in close proximity contribute the most information and pairs at large distance are correspondingly down-weighted. The product of ε for the ith interval and the width of the interval in kilobases ($\varepsilon_i d_i$) corresponds to a distance in linkage disequilibrium units (LDU). Summation of LDUs over successive intervals in a region generates map locations, which, when plotted against the kb scale, delimit regions of extensive LD and LD breakdown. LDU map distances are known to be additive where there is sufficient SNP coverage of a region (Ke *et al*., 2004). Where the LD pattern is fully characterized, the characteristic "block/step" pattern is revealed, with steeper steps denoting more intense recombination and low LD and the plateaus identifying regions with negligible recombination and extensive LD (Figure 1). A useful property of the maps arises because one LDU is equal to one swept radius. One swept radius defines, in effect, a discrete segment on the chromosome within which LD exists above "background" levels. The width of these units (in kilobases) varies

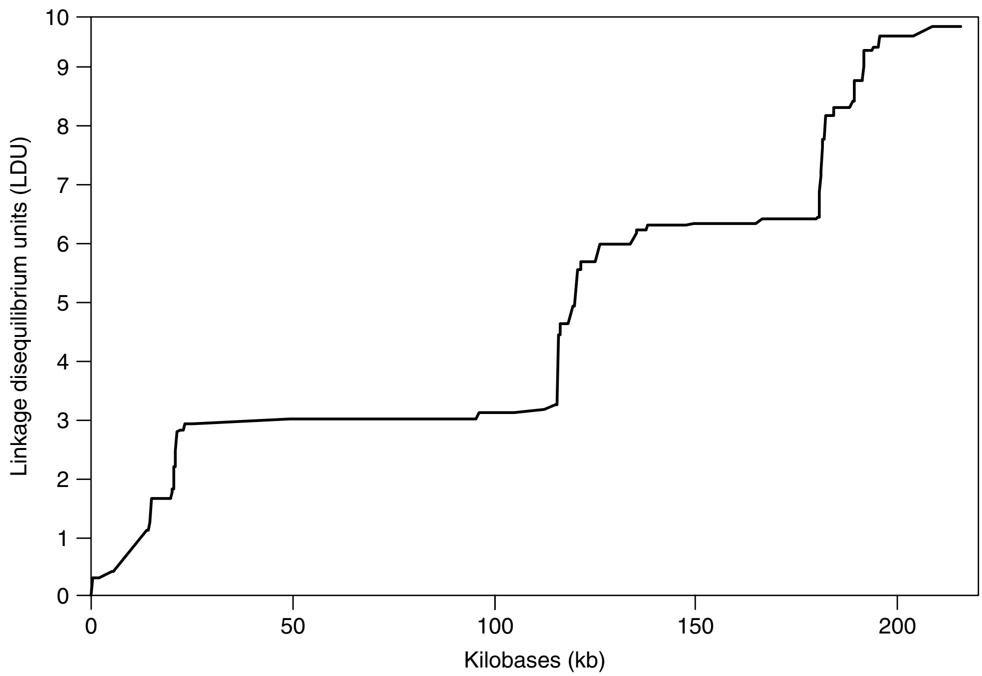

Figure 1 LD map showing characteristic "block/step" pattern of the class II HLA region

extensively across the genome, reflecting the extreme variations in the extent of LD, which is characterized by the LD map. Therefore, effective screening of a candidate region for disease polymorphisms requires even spacing of SNPs on the LDU scale with every LD unit covered. The relationship between power for disease mapping and the numbers and frequencies of SNPs required in each LDU has not yet been established.

There is a high correlation between LDU and cM maps (Figure 2), suggesting that recombination is a major determinant of LD patterns (Tapper *et al*., 2003). The pattern of recombination in different populations is of considerable interest. Most populations (excluding sub-Saharan Africans) are thought to be derived from a relatively small number of founders who moved out of Africa approximately 100 000 years ago. The effect of such population bottlenecks is to create LD, which gradually decays as recombination events are accumulated through successive generations. However, further population bottlenecks (such as those created by famine, war, disease, and migration) will recreate LD in the same way, and so there may be a partly cumulative effect of bottlenecks. Therefore, the observed LD patterns of today reflect a complex interaction between population history, recombination, and other processes. Sub-Saharan African populations, not subjected to the major out of Africa bottleneck, have an LD structure, which reflects more accumulated recombination events. However, because the majority of recombination is concentrated in narrow hot spot regions, which may be between 1 and 2 kb (Jeffreys *et al*., 2000), LD maps differ in length but not pattern (Figure 3, De La Vega

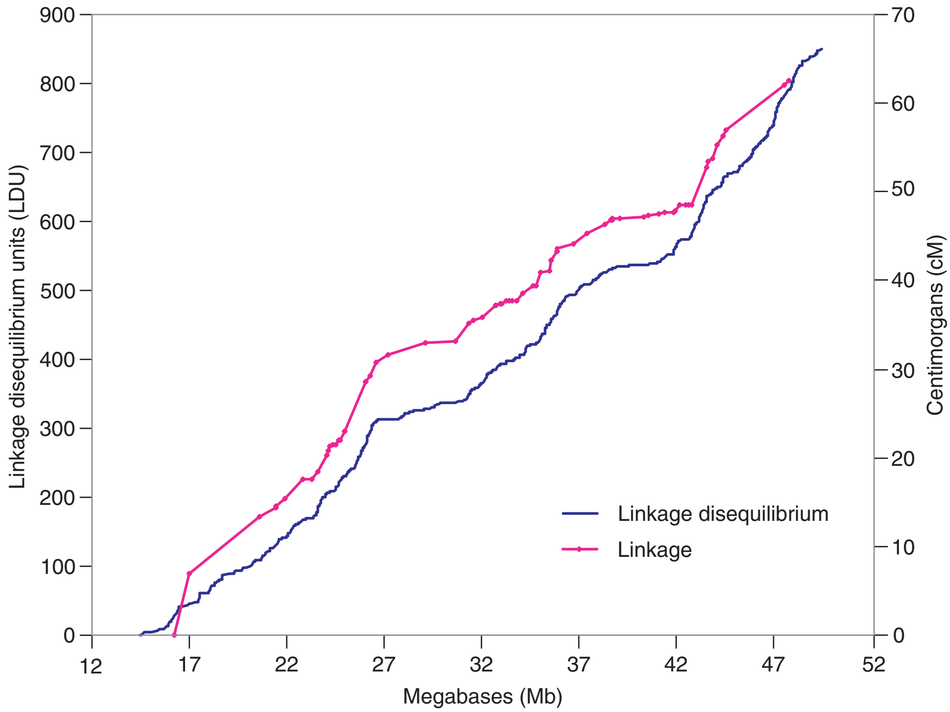

Figure 2 Comparison of the (sex averaged, sequence-based) genetic linkage map to the LD map of chromosome 22 (based on Caucasian samples)

et al., 2003). The increased length of LD maps from populations with African ancestry, reflecting the longer duration, is a consequence of longer steps, reflecting more accumulated recombination events, which are mostly concentrated in hot spots. For these older populations, additional marker typing is required to achieve coverage of all of the LD units in the map. Lonjou *et al*. (2003) found that the contours of different maps are so highly correlated that they suggest the idea of a cosmopolitan map, which may be (linearly) scaled by population-specific "scaling factors". The authors showed that scaling of a map built on data combined across ethnic groups recaptured 95% of the information contained in individual population-specific maps. There is, therefore, potential to develop a unified cosmopolitan LD map of the genome that is useful for all populations irrespective of their underlying haplotype structure (which is known to be very diverse, Jeffreys *et al*., 2000).

3. Linkage disequilibrium maps and positional cloning

The abundance of SNPs and the density at which they may be typed across the genome proffers huge potential for LD mapping of genes for common diseases. Recent estimates predict up to 15 million SNPs in the human genome (Botstein and Risch, 2003). Only a very small proportion of these are likely to have a role in

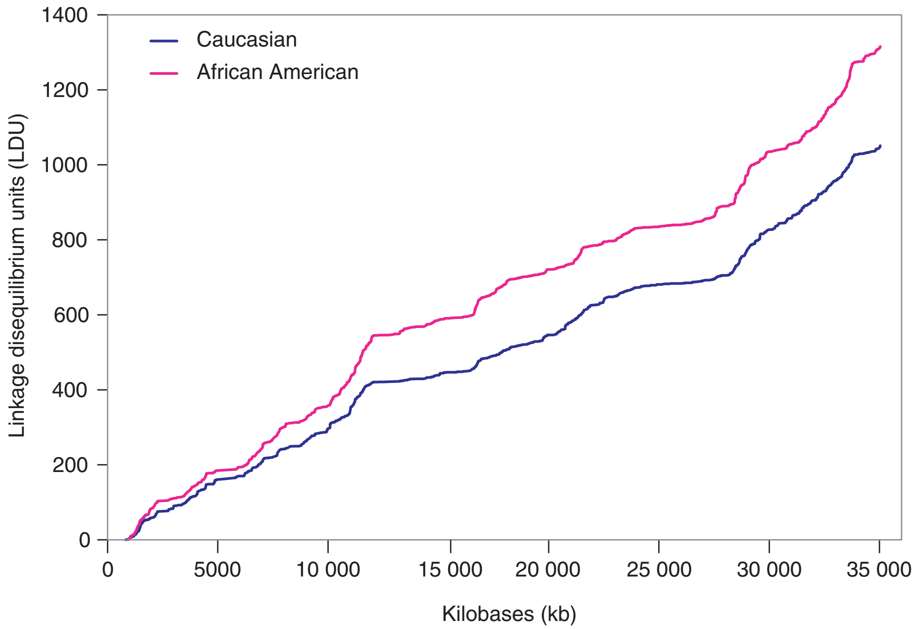

Figure 3 Comparative patterns of linkage disequilibrium across chromosome 22q for Caucasian and African American populations

common human disease. For this reason, LD mapping of disease genes relies on the analysis of multiple SNP markers in the hope of finding a disease association within a narrow genomic region. Simulation studies offer a route to examine the power of these analyses under different scenarios. Maniatis *et al*. (2004) examined the efficiency of LD mapping in a simulation study using a multiple pairwise analysis by the Malecot model, modified to predict the location of a disease-causing variant. The greatest power is achieved when the disease-causing variant is localized on an underlying LDU map, rather than a kb map. The superiority of the LDU scale is particularly evident when the candidate region shows intense recombination hot spots. The next step, which is likely to offer greater power, is to exploit haplotype (rather than multiple pairwise) analysis for localization of a disease polymorphism on an LDU map.

4. Conclusions

There is an increasing body of evidence to suggest that LD patterns are dominated by recombination to the extent that a whole-genome LD analog of the linkage map is useful. One possible route is through the construction of a scale with additive LD units. The colocalization of recombination hot spots in different populations points towards a cosmopolitan "standard" map applicable to all populations, given suitable scaling factors. Simulation studies suggest that there is higher power for multilocus gene localization on the LDU scale. As a minimum, a metric LD map of the genome

will compliment ongoing efforts to represent human haplotype diversity. Strategies that exploit both LD maps and haplotype analysis have the potential to localize genes involved in common diseases with high power.

Short Specialist Review

Finding and using haplotype blocks in candidate gene association studies

Daniel O. Stram
University of Southern California, Los Angeles, CA, USA

1. Introduction

It is well understood that there are limitations to the use of traditional family-based linkage analysis in locating disease genes influencing the risk of complex diseases where no highly penetrant variant with a clearly Mendelian pattern of familial inheritance is evident (Risch and Merikangas, 1996). For complex diseases, large numbers of subjects with disease are required for the statistical analysis of risk factors, whether genetic or not. Particularly for diseases with late age-at-onset, it may be difficult to develop family pedigrees with enough cases to perform traditional linkage analysis. Therefore, studies of either completely unrelated subjects or of parent–offspring trios are increasingly becoming important epidemiological designs for genetic analysis. For the purpose of gene hunting, whether among candidate genes or (as is becoming increasingly possible) whole-genome scans, these studies rely upon linkage disequilibrium (LD) in order to identify the genes or regions involved in disease susceptibility. Key to these studies are the current large-scale investments being made in the mapping of single-nucleotide polymorphisms (SNP) haplotype structure of, initially, particular sets of genes (Cambien *et al*., 1999; Reich *et al*., 2001; Bonnen *et al*., 2002; Crawford *et al*., 2004), and now the entire human genome in the International Haplotype Map (HapMap) Project (The International HapMap Consortium, 2003; *see also* Article 67, **History of genetic mapping**, Volume 4).

Underlying the use of LD-based genetic association studies are four primary assumptions

1. that an important fraction of susceptibility to a given disease may be explained by relatively modest effects of a small number of relatively common variants;
2. that many of these common variants either are SNPs themselves or at least may be thought to arise or mutate at rates no greater than the rate that new SNPs appear;
3. that rates at which SNPs or other variants arise and become common are slow enough that many or most of the carriers today of a given common variant inherited this variant from a single ancestor;

4. and finally that recombination rates are low enough that carriers of a common disease-related variant will also tend to carry a pattern of SNPs that reflects the SNPs that appeared on the ancestral chromosomal locus near to the causal variant.

There are varying degrees of evidence regarding the truth of each one of these assumptions and particular controversy regarding assumption 1, which is often termed the common disease–common variant (CDCV) hypothesis (Terwilliger and Weiss, 1998; Weiss and Clark, 2002). These assumptions plus the recognition that there are millions of common SNPs throughout the human genome, provide a motivation for the study of SNPs in association with human disease (Risch and Merikangas, 1996; Botstein and Risch, 2003). Assumption 4 implies that it is not necessary to genotype the actual causal variant in an association study, since genotyping markers that also fell on the original ancestral locus nearby to the causal variant may pick up some part of the signal of the true causal variant. Once a signal is detected (and found to be replicable in later studies), then further genotyping and/or deep sequencing of high-risk DNA, as well as functional analysis of all variants found, is required to follow-up the association.

Recent discoveries (Daly *et al*., 2001; Jeffreys *et al*., 2001; Gabriel *et al*., 2002) that there is considerable heterogeneity in the amount of LD between SNP markers over the genome and the implication that recombination rates themselves may also be considerably heterogeneous (McVean *et al*., 2004) not only adds to the motivation for conducting association-based testing but also suggests specific analysis strategies and affects the details of the design of such studies. In the remainder of this article, we focus on the implications on association studies of the existence of well-defined "haplotype blocks" covering much of the genome over which there is little evidence for recombination and within which there is limited haplotype diversity (*see* Article 73, **Creating LD maps of the genome**, Volume 4.

2. Haplotype block definition and haplotype diversity

In the manner of Gabriel *et al*. (2002), haplotype blocks are regions in which the standard measure of pairwise linkage disequilibrium (D′) is consistent (or nearly consistent) with no recombination ($|D'| = 1$) for all (or nearly all) pairs of markers in the region, based upon approximate confidence intervals for the statistic. An emerging picture of the human genome is that most of the SNPs in the genome can be defined as falling within haplotype blocks and that between haplotype blocks there are shorter regions in which there is a relatively high level of recombination. Gabriel *et al*. (2002) made an empirical observation that within blocks the number of haplotypes was typically quite limited, with 4–6 haplotypes per block making up approximately 80% or more of all chromosomes. In particular, as more and more common SNPs are genotyped within a block, these will tend to be confined to existing haplotypes rather than splitting existing haplotypes into ever more complex entities. Thus, the number of observed haplotypes (4–6) is expected to be much smaller than the theoretical maximum of $(n + 1)$ nonrecombinant haplotypes among n SNPs. This empirical observation is completely consistent with population

genetics in that, absent recombination, only a fraction of haplotypes arising as new mutations occur are expected to withstand random drift toward extinction. The very high-density SNP discovery and genotyping of 10 regions each of approximately 500 kb in extent (the "ENCODE" regions) as a part of the HapMap project further reinforces the general observations of Gabriel *et al*., with dozens of nearby SNPs often falling upon very few haplotypes.

3. Implications of limited haplotype diversity for association studies

Under assumption 2 above (that common disease-causing variants "behave" like SNPs), it follows that a common causal variant occurring within a haplotype block will fall upon one or more of the common haplotypes, so that a method of predicting common haplotypes and assessing each one (and/or each combination) of them for risk should be sensitive to the presence of an unmeasured causal variant. In its idealized form, each block is separated by regions of high recombination between haplotypes so that it is possible to estimate the haplotype-specific risk associated with haplotypes in each block as if they are independent between blocks. This approach has formed the basis of the haplotype-specific risk estimation methods used by several groups (Haiman *et al*., 2003; Karamohamed *et al*., 2003; Prince *et al*., 2003; Sai *et al*., 2003), which seek to detect and localize to a particular block the signal of an unmeasured variant. In the following, we outline the following three steps in performing these association studies.

1. SNP and Haplotype discovery
2. Picking of haplotype-tagging SNPs (ht SNPs) for large-scale genotyping (e.g., in a case-control study)
3. Testing and estimation of haplotype-specific risk in a large-scale case–control study.

4. SNP and haplotype discovery

In the initial stages of an association study, a large number of SNPs are identified and genotyped in a "haplotype discovery panel" comprising a relatively small number of subjects. Some groups (Carlson *et al*., 2003; Chapman *et al*., 2003) have relied upon deep resequencing of DNA for the subjects that make up the haplotype discovery panel. Other studies rely upon the use of public or private databases to determine which SNPs may be available. Even with the public availability of large numbers of SNPs (nearly 7 million being deposited in dbSNP **http://www.ncbi.nlm.nih.gov/SNP/** as of this writing), there has, up to this point, been a considerable amount of work required in assembling a suitably dense panel of SNP markers for which assays can be developed for any specific genotyping platform and which are frequent enough so as to be useful in the pursuit of common causal variants, and intensive efforts to discover SNPs by deep resequencing of candidate genes for various diseases are currently underway (Crawford *et al*., 2004).

Currently, several important projects (Olden and Wilson, 2000; The International HapMap Consortium, 2003), the largest of which is the International HapMap Project, are considerably reducing the difficulty of determining which SNPs are suitably polymorphic, and are providing a dense network of SNPs for haplotype discovery.

Haplotype discovery consists of genotyping the selected markers in the DNA for the subjects that comprise the haplotype discovery panel and then assessing haplotype structure. Two key issues are how large the haplotype discovery panel (how many subjects) should be and how dense a network of SNPs is needed to be fully informative about haplotype structure. Up to the advent of the HapMap, this was a problem that was dealt with on a study-by-study or group-by-group basis. It is expected that the DNA genotyped by the HapMap (from 45 to 90 individuals depending upon ethnic group) will essentially play the role of the haplotype discovery panel used by most association studies in the future, with an SNP density now expected to vary between 1 SNP every 2.5–3 kb throughout the entire genome.

5. Haplotype block structure and ht SNP selection

The most popular criteria for defining haplotype blocks appears to be the Gabriel *et al*. (2002) method, which bases its block definition upon upper and lower confidence limits for $|D'|$. Other approaches toward block definition either rely upon slightly different LD measurements (e.g., the 4-gamete test) to define regions of limited recombination, or focus instead directly upon finding regions of limited haplotype diversity (Patil *et al*., 2001; Zhang *et al*., 2002), irrespective of recombination. A helpful review of these procedures is provided by Wall and Pritchard (2003a).

A number of criteria have been chosen for ht SNP selection, these may broadly be broken into methods that seek to optimize SNP prediction (Chapman *et al*., 2003; Meng *et al*., 2003; Weale *et al*., 2003; Carlson *et al*., 2004) versus prediction of haplotypes (Ke and Cardon, 2003; Sebastiani *et al*., 2003; Stram *et al*., 2003a). The first group of methods focuses upon the statistical prediction of the specific SNPs that were genotyped in the haplotype discovery panel. That is, they seek a set of ht SNPs that when genotyped can be used to predict the remaining ungenotyped SNPs. These methods are most appropriate when the candidate loci in question have been fully resequenced during SNP discovery in a large enough number of subjects so that the variants found may be thought to constitute a complete census of all common mutations in these genes. Efforts to provide such a census of all polymorphisms, for genes considered most important in specific diseases is continuing (Crawford *et al*., 2004); however, this is a daunting task in general. When the SNPs found in the discovery phase cannot be considered to be an entire census of all variation, it may be more relevant to concentrate on the prediction of common haplotypes, with the presumption that common unmeasured causal variants must fall upon common haplotypes, although statistical assessment of haplotype prediction versus SNP prediction has not yet been completely explored.

Within haplotype blocks, it is relatively easy to compute the predictability either of SNPs or of common haplotypes, based upon a given set of SNPs, which will

be chosen to be measured as ht SNPs in a latter association study. A standard approach is provided by Stram *et al*. (2003a). This consists of (1) the estimation of haplotype frequencies within the block and (2) the computation of the squared correlation between measured ht SNPs genotypes and haplotypes or non–ht SNPs. In both cases, the best predictor of the number of copies $\delta(H) = 0$, 1, or 2 of a given haplotype or unmeasured SNP is computed as the conditional expected value $E\{\delta(H)|G_{ht}\}$ of $\delta\ (H)$ given any ht SNP genotype, based upon the haplotype frequency estimates. The squared correlation between the true and predicted value of $\delta(H)$ is then computed by enumeration over all possible ht SNP genotypes.

This calculation forms the basis of the ht SNP selection methods of Stram *et al*. (2003a). SNPs are selected as ht SNPs depending upon the degree to which their inclusion increases this R^2 measure. A program (tagSNPs) that maximizes the minimum R^2 for either the common haplotypes or for unmeasured SNPs using a modified forward selection algorithm is available (**http://www-rcf.usc.edu/~stram/tagSNPs.html**).

The value of any ht SNP selection method is dependent upon there being restricted haplotype diversity in the region of interest. The block definitions of Gabriel *et al*. (2002) provide boundaries of regions wherein it is expected that haplotype diversity is indeed quite restricted. Outside the regions of restricted haplotype diversity, ht SNP selection methods will fail to adequately capture the variability of SNPs and haplotypes. The decision of whether to include SNPs that lie within regions of low LD depends on whether they are of special interest in and of themselves (e.g., missense SNPs) or if they are a part of a complete census of common variation (e.g., from deep resequencing studies) of the locus of interest. Of course, as the HapMap and other projects reach very high densities of SNP genotyping, it will be increasingly reasonable to regard the SNPs that have been characterized as representing, if not a complete census, then a least a considerable fraction of all genomic variation that may be functionally related to disease.

6. Testing of haplotype-specific risk

We now consider the statistical testing and estimation of haplotype-specific risks of disease for each common haplotype within each haplotype block, with our interest focused upon the use of the case–control study data. The methods described here are based on those described in Schaid *et al*. (2002), Zaykin *et al*. (2002), and Stram *et al*. (2003b). After genotyping ht SNPs for the case–control study subjects, the ht SNP genotype data for the cases and controls are combined to estimate ht SNP haplotype frequencies using the same EM (or PLEM) algorithm that was used in the discovery panel. Upon convergence of the EM algorithm, the estimated haplotype type counts $E\{\delta_h(H)|G_{ht}\}$ are computed for each individual i as

$$E\{\delta_h(H)|G_{ht,i}) = \frac{\sum\limits_{H\sim G_{ht,i}} \delta_h(H) p_{h_1} p_{h_2}}{\sum\limits_{H\sim G_{ht,i}} p_{h_1} p_{h_2}} \qquad (1)$$

where $H \sim G_{ht,\mathrm{i}}$ refers to the ht SNP haplotype pairs (h_1, h_2), which are compatible with the ht SNP genotype data $G_{ht,\mathrm{i}}$ for the individual in question. These estimated haplotype counts are computed for each individual and each common haplotype, and these are merged with the outcome data (disease status) and other covariates (age, sex, etc.), which may be required in the analysis. Finally, logistic regression analysis is used to analyze the data with the $E\{\delta_h(H)|G_{ht}\}$ treated as if they are equivalent to the true haplotype counts in the analysis. In particular, Zaykin *et al.* (2002) describe the formation of unbiased score and likelihood ratio tests for the null hypothesis that the haplotypes are not associated with increased risk of disease against a log-additive alternative. These tests are available in any standard logistic regression program, and these programs allow considerable flexibility in the inclusion of other covariates (age, ethnicity, known risk factors, etc.) into the analysis.

The score or likelihood ratio tests mentioned above are closely related to the optimal score statistics described from likelihood theory for generalized linear models by Schaid *et al.* (2002), and as such they represent efficient tests of the null hypothesis that there is no association between haplotypes and disease status. They can be conducted as single degree of freedom tests in which the per-copy risk associated with carrying one copy of a given haplotype is compared to carrying zero copies of the same haplotype (so that the baseline category becomes "all other haplotypes"), or can be used to test the global null hypothesis that no haplotypes are related to risk, with the most common haplotype generally nominated to serve as the baseline category.

7. Estimation of haplotype type–specific risk

In the above, we have concentrated upon the testing of null hypotheses (of no haplotype-specific risk) rather than on estimation of risk. For testing purposes, the analyses given in Zaykin *et al.* (2002) indicate that we are justified in ignoring the uncertainty of haplotype type count estimation (see also Tosteson and Ware, 1990; Stram and Kopecky, 2003, for similar results in other settings). On the other hand, estimation of haplotype-specific risks is affected by haplotype count uncertainty. Such uncertainty affects confidence interval estimation, comparisons of nonzero haplotype-specific risks between two or more haplotypes, and evaluation of the significance of gene–environment interactions. These biases arise for two basic reasons (Stram *et al.*, 2003b), the first is that the haplotype frequency estimates, p_h, from the EM algorithm, used to calculate the haplotype count variables in equation (1) are subject to sampling variation, which has been ignored, and second, that case–control selection implies that high-risk haplotypes are overrepresented in case-control studies leading to biased estimates of the haplotype frequencies used in that calculation. Some headway has been made on dealing with these two issues directly (Epstein and Satten, 2003; Stram *et al.*, 2003; Zhao *et al.*, 2003). However, for large case–control studies using a block-based approach, these biases are generally quite minor. Limited recombination between the SNPs within a block implies little inherent uncertainty in ht SNP haplotype prediction, and the large sample sizes needed in the case–control study minimizes sampling variability in the haplotype frequency estimates for the ht SNPs. Only when very

high haplotype-specific risks are present, does overselection of high-risk haplotypes lead to perceptible bias in either haplotype risk or confidence limit estimation. This observation also implies that the logistic regression methods may be applied to other problems as well, such as the testing and estimation of haplotype by environment or haplotype by haplotype interactions (Kraft *et al*., 2004), greatly enhancing the attractiveness of the logistic regression approach over methods which simply seek to quantify differences in haplotype frequency between cases and controls.

8. Other issues

Other important practical considerations must be encountered in every analysis. These include:

1. What to do with uncommon haplotypes?
2. What if a log-additive model is not of primary interest?
3. What should be done about SNPs that do not fall within blocks?

8.1. Uncommon haplotypes

Approaches used with uncommon haplotypes have included the pooling of all the uncommon to form a separate category, which is then treated as a single "haplotype" in the logistic regression or probably more reasonably, to pool a given uncommon haplotype with the common haplotype that is most similar to it (Thomas *et al*., 2003). Within a haplotype block the uncommon haplotypes (those of frequency less than 5–10%) are expected to make up no more than about 10–20% of all the haplotypes, so that this is less of a problem within blocks than without (see below).

8.2. Other penetrance models

The efficient score test for other penetrance models than the log additive can be computed in the same manner as described above, except that the expected haplotype count variables are replaced with expected indicator variables, for example to test a purely dominant effect of a particular haplotype one would modify equation (1) to compute

$$E\{I_h^D(H)|G_{ht,i}) = \frac{\displaystyle\sum_{H\sim G_{ht,i}} I(\delta_h(H) > 0)\, p_{h_1} p_{h_2}}{\displaystyle\sum_{H\sim G_{ht,i}} p_{h_1} p_{h_2}} \qquad (2)$$

for each member of the case–control study, with this variable then merged with the case–control status and used as before. More generally, codominant models may be tested for and estimated by computing the expectations of indicator variables for $\{\delta_h(H) = 1\}$ and $\{\delta_h(H) = 2\}$ separately, and again merged with the

case–control data. As with the log-linear model, tests of the null hypothesis of no haplotype-specific risks remain valid despite uncertainty in estimation of the indicator functions, and within haplotype blocks the precision of estimation of these functions is very high.

8.3. Models for quantitative phenotypes

The same general approaches outlined above can be applied towards quantitative outcomes so that, for example, standard linear regression software can be used to analyze the relationship between haplotypes and mean response of measured outcomes. The same principles apply, that is, both univariate and global tests of any relationship between haplotypes and outcomes are unbiased under the null hypothesis, and within regions of restricted recombination, confidence intervals for either haplotype, main effects, or their interactions with other variables are generally quite reliable.

8.4. Multiple testing

In studies in which a large number of haplotype blocks are being evaluated (e.g., in a complex gene or large set of genes), the nominal p-value for any given block-specific test of the relationship between haplotypes and disease may be a very poor reflection of the overall statistical significance of the study as a whole. When haplotypes within blocks are independent, then a simple Bonferroni correction of each of the block-specific p-values (i.e., multiplying the global p-value within each block by the number of blocks considered in the analysis) is a simple and often quite accurate approach toward correcting for multiple testing. The extent of recombination between haplotypes in nearby blocks varies widely; however, in many cases, haplotypes may be very highly correlated across neighboring blocks. In this, the Bonferroni test may be overly conservative since fewer genuinely independent tests are really being performed.

One attractive approach for dealing with this issue is permutation testing. In this procedure, the permutation distribution of the smallest block-specific p-value is developed by randomly switching case-control status a large number of times for each individual in the study (keeping the total number of cases and controls the same in each switch). The observed smallest p-value is then compared to the permutation distribution and if it falls within the extreme tail of the distribution then the result is considered significant, that is, if the observed value is smaller than α percent of the permuted values, then the test is significant at the $1-\alpha$ level of confidence. This procedure is complicated when the logistic regression is to be corrected for the influence of other covariates in the analysis (since case–control status should be permuted only between otherwise similar subjects) and can be time consuming for large studies. An alternative is simply to merge blocks that are very highly correlated with each other prior to the Bonferroni test or even to put all haplotypes in all blocks into a single model and perform a single global test.

9. The extent of coverage of haplotype blocks

Looked upon on a gene-by-gene or region-by-region basis, it is clear that there is considerable local variation in haplotype block structure (Wall and Pritchard, 2003a). Candidate regions in which little or no LD is seen between nearby markers are not, currently, good prospects for SNP or SNP-haplotype-based association testing. Unless a very complete survey of SNPs is available for such regions, there is little hope that the SNPs selected will capture signals from causal variants. Even when such a survey is available, the costs of genotyping every common SNP in candidate gene regions where there is little LD may be prohibitive – although genotyping costs are now dropping rapidly.

The most important issues in the implementation of haplotype block-based association studies are those regarding the number, size, and coverage of blocks over typical candidate gene regions or the genome as a whole. Recent surveys (Wall and Pritchard, 2003b; Crawford *et al*., 2004) have indicated that apparent haplotype block structure becomes more complicated as the density of SNPs increases; specifically, as the density increases, the average length of haplotype blocks decreases, because regions that initially did not appear to have been in blocks are found to show high levels of LD over short ranges as more SNPs are genotyped.

Until now, it was difficult to judge the fraction of all SNPs that are contained within haplotype blocks over the entire human genome, or the number of ht SNPs that would be required for well powered association-based genome-wide scans. However, with the advent of the HapMap project, the resources for just such a survey are rapidly becoming available, first for populations of European origin and soon for other ethnic groups. It now seems likely that considerably more ht SNPs will be needed for most studies than it appeared when the first reports of the existence of haplotype block structure were published. Advances in high-throughput genotyping imply, however, that even if very dense networks of ht SNPs are required for candidate gene or genome-wide association-based studies, this will not be the ultimate limiting factor determining their feasibility. As a detailed haplotype structure is developed by the HapMap and assuming that genotyping costs continue to drop rapidly, it may soon be possible to consider an optimized whole-genome-wide scan in which ht SNPs are selected within blocks supplemented by all known common SNPs in low LD regions. This would allow a hybrid approach towards case-control analysis, exploiting haplotype structure over most of the genome while performing individual tests on the remaining low LD SNPs. Very large case–control studies will be needed in order to exploit this approach while controlling adequately for false-positive associations.

Short Specialist Review

Avoiding stratification in association studies

Bernie Devlin
University of Pittsburgh, Pittsburgh, PA, USA

Kathryn Roeder
Carnegie Mellon University, Pittsburgh, PA, USA

When hunting for genetic variants (*see* Article 68, **Normal DNA sequence variations in humans**, Volume 4) affecting liability to complex disease, ideal study designs are those amenable to recruitment of large samples, thereby increasing power, and amenable to seamless modeling of both environmental and genetic factors, thereby capturing as many of the sources of variability as possible (*see* Article 69, **Reliability and utility of single nucleotide polymorphisms for genetic association studies**, Volume 4). One solution is provided by association studies (Risch and Merikangas, 1996; Risch, 2000). Association analyses can be conducted by using either family-based samples or population-based samples. The simplest type of population-based association study involves genotyping SNPs in a sample of cases and controls. For each SNP, the strength of the association is assessed using a chi-squared test. In a random mating population, the only SNPs associated with the disease will be those that are tightly linked with a liability allele (LA).

Human populations, however, often exhibit substructure because of nonrandom mating, such as that based on proximity or culture (*see* Article 71, **SNPs and human history**, Volume 4). This substructure, or stratification, creates concern about the validity of association tests (Knowler *et al*., 1988; Lander and Schork, 1994). The problem arises when (1) the allele frequencies vary across subpopulations making up the study population; (2) the prevalence of the disease varies across subpopulations; and (3) these two factors coincide to create associations between phenotypes and genotypes that are not linked to LAs. For example, imagine a worst-case scenario in which affected individuals were selected from subpopulation A and unaffected individuals from subpopulation B; any alleles at higher frequency in A than in B will be spuriously associated with affection status; the greater the differential between A's and B's allele frequencies, the greater the association will appear.

By using the transmission of alleles from parents to offspring, the family-based approach completely removes concerns about population substructure. Since Spielman *et al*.'s (1993) seminal paper, and Ewens and Spielman's (1995) more

rigorous demonstration of Transmission Disequilibrium Test or TDT's robustness to substructure, the number of family-based tests has grown tremendously (Lange and Laird, 2002a,b). A substantial advantage of the family-based design is the robustness to population structure. A substantial disadvantage is that the design can hinder recruitment of large samples. For late-onset diseases, such as the Alzheimer disease and cardio-vascular disease, it is very challenging to collect family-based samples, whereas for childhood-onset diseases such as autism, it is much more natural.

In an effort to discover LAs with small effect, large, population-based samples and large-scale genotyping are being used to evaluate disease/gene associations. To use these study designs, it is desirable to account for the effect of population stratification, thereby avoiding evaluation of many spurious associations.

The effect of stratification is to inflate the test statistic by a multiplicative factor, λ, which is typically greater than 1 if population substructure, admixture, or cryptic relatedness are present in the sample. The magnitude of the effect can be expressed as a linear function of heterogeneity in allele frequencies and disease prevalences among subpopulations and the sample size (Devlin and Roeder, 1999). For instance, in a poorly designed study including equal fractions of two, moderately divergent populations, for which the disease prevalence is twofold higher in one ethnic group, the test is essentially on target for samples of size 100, but 50% inflated for samples of size 1000. Notice that this effect could be removed either by matching cases and controls by ethnic origin or by using a stratified method of analysis (but that assumes the individual populations are themselves homogeneous). However, if the ethnicity was not recorded, these options are not available.

Until recently, few definitive examples of studies in which population substructure has led to spurious association have been identified (Knowler *et al*., 1988; Thomas and Witte, 2002). This may be due, in part, to the limited size of most samples to date. Stratification can have a marked effect on the false-positive rate of tests that are not corrected for this feature in large samples, even if small sample investigations of the same populations show little evidence of structure (Devlin and Roeder, 1999; Devlin *et al*., 2001a). Because association studies are increasingly being performed on much larger samples, the effect of stratification is likely to become more evident (Freedman *et al*., 2004; Marchini *et al*., 2004).

On the basis of the observation that population substructure can cause spurious associations between phenotype and alleles at an unlinked locus, Pritchard and Rosenberg (1999) suggested evaluating a large number of loci unlinked to the candidate gene of interest, which we might call "null loci", to determine if there is evidence of association, indicating substructure a priori. However, because all human populations are stratified to some degree, association will be detected, almost surely, as the sample size or the number of loci tested increases. As in many situations in practice, it will be more fruitful to estimate the size of an effect than to test for its presence. Building on results from evolutionary theory (e.g., Wright (1969); Lewontin and Krakauer (1973)), Devlin and Roeder (1999) demonstrated that the effects of stratification on test statistics of interest are essentially constant across the genome, under certain conditions. On the basis of this finding, they suggested using null loci located across the genome to estimate the effect of stratification and then removing the effect from the association test statistic.

Currently, two methods build on the idea of using the genome to correct for stratification in the population: genomic control (GC) (Devlin and Roeder, 1999; Bacanu *et al*., 2000, 2002; Reich and Goldstein, 2001) and structured association (SA) (Pritchard *et al*., 2000a,b; Satten *et al*., 2001; Falush *et al*., 2003; Hoggart *et al*., 2003). The GC approach exploits the fact that population substructure inflates statistics used to assess association. By testing multiple polymorphisms throughout the genome, only some of which are pertinent to the disease of interest, the degree of overdispersion generated by stratification can be estimated and taken into account. The SA approach assumes that the sampled population, while heterogeneous, is composed of subpopulations that are themselves homogeneous, or is an admixture of such subpopulations. By using multiple null polymorphisms throughout the genome, this "latent class method" estimates the probability that the sampled individuals derive from each of these latent subpopulations. It is then possible to condition on subpopulation and remove the effect of stratification.

The GC approach is exceptionally simple to implement: compute the desired test statistic for each candidate marker and each null marker; then estimate the magnitude of the inflation factor λ and divide the candidate test statistics by this quantity before computing p-values. This general approach can be applied to single-locus tests (Devlin and Roeder, 1999), multilocus linear models (Bacanu *et al*., 2002), tests based on haplotypes (Tzeng *et al*., 2003a,b), and tests based on pooled genotyping (Devlin *et al*., 2001b).

A limitation of the GC approach is that it assumes that the effect of stratification is approximately constant over all loci. This assumption is generally supported both theoretically and empirically (Bacanu *et al*., 2000). It is violated only when the loci under study are under strong selective pressure (Robertson, 1975). Specifically, it is required that the locus under investigation is not under differential selective pressure in different subpopulations. Examples of genes under such selection include those coding for pigmentation, malarial resistance, and lactose tolerance. Notice that for some genes this assumption may be violated in some populations, say African Americans, but not for others, such as Northern Europeans. In addition, the assumption is required only for candidate loci. Null loci can violate this assumption without increasing the false-positive rate.

Rather than correcting for population substructure by estimating the effect of stratification, the general idea behind the simplest SA model is to cluster the samples into groups with similar genetic ancestry and then to condition upon this ancestry covariate. For Pritchard *et al*.'s (2000a,b) method, a Bayesian clustering program is run to determine both the number K of subpopulations within the population and the membership probability vector for each individual. Model choice for K is performed by running a Markov chain separately at different values of K and an approximate method is used to estimate posterior probabilities for each value of K. The program STRUCTURE performs this task (Pritchard *et al*., 2000b). As output, one obtains a vector $q = q_1, \ldots q_K$ that indicates an estimate of the fraction of the individual's genome that originated from each of the K subpopulations.

Given an estimated membership vector for each of the subjects in the study, the next step is to compute a likelihood ratio test based upon computing the likelihood of the data under the null and alternative hypotheses (Pritchard *et al*., 2000a). Under the null, it is assumed that the genotype of the candidate gene is independent of

the case/control status of the subject. Under the alternative, the model is quite flexible, allowing any genotype to be associated with case status; the model does not necessarily restrict the association to be constant across subpopulations. In this second phase of the analysis, both K and the membership vectors are treated as known quantities. To assess significance, a smoothed bootstrap is recommended. The program STRAT uses the output from STRUCTURE as input in conducting a test for association.

STRUCTURE can also be run holding K fixed; however, if the wrong value is chosen, the results can be quite misleading. For instance, if all the individuals are from a single population but K is set at 2, then the program will estimate that all the people are about a 50% mixture of each subpopulation. As a consequence, the power of the association analysis can be greatly diminished. Alternatively, if K is too small, the size of the test will be inflated.

The simplest SA model described above can be extended to allow for admixture. In this case, rather than presuming that each individual is a member of one of the subpopulations making up the population, the admixture model allows each person to have ancestry from multiple subpopulations. Now, the membership vector estimates the fraction of their chromosomal material from each source. In practice, this model is quite similar to one developed for admixture mapping (*see* Article 76, **Mapping by admixture linkage disequilibrium (MALD)**, Volume 4) (McKeigue *et al*., 2000; Hoggart *et al*., 2003). Indeed, some improvements over the 2-stage process of modeling employed by Pritchard and colleagues have been achieved in competing implementations (Satten *et al*., 2001; Zhu *et al*., 2002; Hoggart *et al*., 2003; Zhang *et al*., 2003; Chen *et al*., 2003).

More recently, the admixture models have been extended to allow for correlation due to "admixture linkage", which is defined as the spatial correlation across markers due to ancestry from a common subpopulation. With this additional feature, the methods can handle markers that are fairly densely spaced along the chromosome, but not so dense that the marker alleles are highly dependent at the population level (*see* Article 73, **Creating LD maps of the genome**, Volume 4).

Even with decreasing genotype costs, inclusion of null markers comes at a substantial cost, especially for large studies. Although it is unclear how many null markers are required in any given study, whether the analysis will be conducted using SA or GC (Bacanu *et al*., 2000; Pritchard and Donnelly, 2001; Marchini *et al*., 2004), it is worth considering how to minimize the number of null markers required. In some situations, SA can benefit from the use of markers known to differ substantially between subpopulations (see Satten *et al*., 2001; Hoggart *et al*., 2003). For instance, loci conferring malarial resistance or markers in tight linkage disequilibrium with these loci often have allele frequencies that differ substantially between Africans and Europeans. Thus, when studying an African-American population, such loci should be more informative than randomly selected markers. When studying populations composed of widely divergent ethnic groups originating from different continental groups, a targeted approach can greatly reduce the number of required markers to achieve separation by perhaps an order of magnitude. The Haplotype Map project, which is producing data from a huge number of SNPs in three geographically distinct population samples, will surely provide many SNPs with allele frequencies that differ substantially among these

populations. The usefulness of such attempts, however, is less apparent when the population under investigation has subtle effects of structure. For instance, there are no proven methods for preselecting informative null loci within a Caucasian population. Rosenberg *et al*. (2003) do provide calculations on the informativeness of various marker types.

In contrast, markers under targeted selection are not appropriate for GC, which performs best with the use of representative null markers. However, it is permissible to utilize both candidate and null markers to estimate λ with this approach. This is permissible for the following reasons. Even if several of the candidate genes impart a signal, the signal typically does not extend past a narrow region of linkage disequilibrium. Thus, many markers in the candidate genes will yield a null signal. This information is helpful in estimating the effect of stratification. Provided λ is estimated using a robust estimator, the bias arising from including candidate genes is minor. Consequently, in a study investigating many candidate genes, implementing GC can involve a very minor additional expense; see the original Devlin and Roeder (1999) paper for a Bayesian analytic approach for such data.

Although similar in conception, GC and SA have different strengths and weaknesses. The SA approach is more ambitious, attempting to infer the genetic ancestry of each individual sampled, and may require more null loci to ensure a successful outcome (Pritchard and Donnelly, 2001). When too few null loci are used, K may be underestimated, which can cause the method to be anticonservative. Assuming that the population structure can be reconstructed, however, this approach has the capacity to model different effects in different subpopulations. This extra flexibility leads either to a gain in power or a loss, depending upon whether it is needed to model the data appropriately. Certainly, it is biologically plausible that effects could vary across subpopulations. It is difficult to predict it a priori.

In a sense, the GC approach is more general because it corrects for confounding due to cryptic relatedness as well as population substructure and admixture. The SA approach assumes that the observations are independent, conditional upon the inferred genetic associations due to population substructure and admixture. Consequently, the SA approach is not valid for isolated or inbred populations, which tend to have substantial amounts of cryptic relatedness.

In most published simulation studies, the average rejection rates for GC were close to the nominal values (Bacanu *et al*., 2000; Pritchard and Donnelly, 2001; Devlin *et al*., 2001b). The exception is Marchini *et al*. (2004), who explored the performance of GC over a bigger range of conditions, including the extreme tail of the distribution ($<10^{-4}$). They found that GC does not provide a perfect correction in the extreme tails of the distribution. This feature occurs largely because GC treats λ as a known constant (Reich and Goldstein, 2001) and because the variability in the estimate of λ matters for small α. They also considered studies with a high level of population heterogeneity and greatly varying disease prevalence, which are not taken into account in the experimental design or analysis. These are conditions under which the GC method is not recommended, because it will likely have low power. On the other hand, it is simple to calculate correct tail probabilities if a researcher wishes to use extremely small critical values (Devlin *et al*., 2004).

Owing to the high computational demands, the SA method has not been thoroughly investigated, especially in the tail of the distribution and for large sample sizes. Thus far, it appears to be well calibrated, provided sufficient null loci and/or subjects have been included from which to determine K. The method has an inflated false-positive rate when K is underestimated. For instance, in studies including only individuals of European descent, the method typically yields $K = 1$, in which case no correction is provided for the subtle levels of stratification in the sample.

Regarding power, the best choice of analysis for any particular dataset depends primarily on the level of expected population heterogeneity. With a moderate amount of substructure, both methods can outperform TDT in that the power, per person recruited, is generally greater for both the GC and SA methods than it is for the TDT (Bacanu *et al*., 2000; Pritchard *et al*., 2000a; Pritchard and Donnelly, 2001). The notable exception occurs in admixed populations where the TDT receives an extra boost in power (Ewens and Spielman, 1995). Limited simulations have been performed by Pritchard and Donnelly (2001), comparing SA and GC. From these simulations, it appears that GC is more powerful than SA when the allelic effect is nearly constant across subpopulations; however, if the effect varies strongly across subpopulations, particularly if a different allele is associated with the disease, SA is more powerful than GC.

The SA method is well designed to capture the larger scale heterogeneity found in admixed populations, such as African Americans, or in studies where the subjects are not carefully screened for ethnicity. It is in these heterogeneous settings that the flexible parameterization of allelic effects is likely to pay off. For instance, a marker allele may be in LD with the causal polymorphism in the European subpopulation but not in LD in the African subpopulation. Without the flexible parameterization typically employed in the SA method, the effect can be muted.

In carefully designed studies, with fairly homogeneous populations, however, a large number of null loci will be required before SA can detect unrecorded subpopulations. In addition, in these populations, it is difficult to construct biologically plausible motivation for different allelic effects across subpopulations. Consequently, SA may not be the method of choice in this type of setting.

In contrast, GC was designed to be applied to studies in which careful efforts have been made to obtain a fairly homogeneous sample (Devlin and Roeder, 1999; Bacanu *et al*., 2000). When applying GC, the power of the analysis will be enhanced if efforts are made to match the cases and controls for ethnicity (Lee, 2004), thus further removing the effect of heterogeneity. In application, GC adjusts for the remaining effects of stratification that cannot be removed by careful planning of the study. While the GC approach is approximately valid in highly heterogeneous populations, in this situation, the power of the test may be low because the inflation factor can be large.

Owing to the plummeting costs of SNP genotyping (*see* Article 77, **Genotyping technology: the present and the future**, Volume 4) and the availability of nearly a million validated SNPs from the Haplotype Map project, it seems reasonable to predict that whole-genome association (WGA) scans for LAs are in our future. In fact, to our knowledge, a handful of WGA scans have been performed or are in progress. Consider the following scenario. A research team wishes to perform a WGA scan in which hundreds of thousands of markers are to be genotyped on a

sample of mixed European ancestry, with the sample consisting of a 1000 affected and a 1000 unaffected individuals. How should the researchers design/implement the study? Hinds *et al*. (2004) provide one elegant approach. They propose to use several hundred SNPs, which have been selected because they show subpopulation variation in their allele frequencies, to match case- and control-individuals for genetic ancestry (using, e.g., SA or other clustering algorithms). This first-phase analysis would be performed on more than 2000 case- and control-individuals to optimize matching for the sample to be used for WGA. Now, perform the massive genotyping on the matched sample and analyze the data using standard methods for matched designs. As also shown by Lee (2004), Hinds *et al*. (2004) find that power is greatly enhanced over analyses ignoring population structure.

Is there a way to use the logic of GC to account for any residual impact of structure after WGA using matched samples? Lee (2004) shows how the standard approach to GC achieves this goal for a single locus. For experiments involving a large number of tests of genetic markers, such as WGA, one should analyze the entire distribution of test statistics (Devlin and Roeder, 1999; Tzeng *et al*., 2003a). In addition to the Bayesian methods developed in Devlin and Roeder (1999), we are currently developing new GC methods for this setting.

Short Specialist Review

Mapping by admixture linkage disequilibrium (MALD)

Michael William Smith
SAIC-Frederick, National Cancer Institute at Frederick, Frederick, MD, USA

Differentiation of the peoples of the world over the past 100 000 years (*see* Article 6, **The genetic structure of human pathogens**, Volume 1) coupled with prehistoric and more recent mass migrations in the past few hundred years have resulted in different peoples coexisting, intermarrying, and generating populations of mixed origins (Figure 1). Genetically speaking, this is termed *Admixture*, reflecting the more and more common occurrence of individuals from previously separated and differentiated populations producing an intermingled group of offspring that are then a population of mixed ancestry. Since we know that most (85–90%) of the genetic variation in humans is shared across continental groups (Lewontin, 1972; Rosenberg *et al*., 2002), the remainder provides the basis of differentiation between groups and a nonrandom basis to the chromosomes and chromosomal segments in these admixed populations.

During the times since the major continental groups populations were isolated from one another, genetic differentiation naturally occurred through the processes of genetic drift, bottlenecks, and selection. Upon subsequent contact and the concomitant genetic mixing, admixture generates long-range linkage disequilibrium initially on the order of tens of centimorgans due to long stretches of chromosomes that were derived from either contributing population, and was originally described as mapping by admixture linkage disequilibrium (MALD) (Briscoe *et al*., 1994; Chakraborty and Weiss, 1988; Stephens *et al*., 1994; McKeigue 1997). The chromosomal segments from each parental population become smaller and smaller as a function of time since admixture began because of recombination, although with continuous gene flow large unbroken segments are continually added from the parental populations (Figure 2).

Naming has proven controversial, with one group suggesting Admixture Mapping as being more descriptive (Halder and Shriver, 2003; Hoggart *et al*., 2004), yet continuity of the literature and historical precedence supports the original MALD as the general term for the gene discovery method. The MALD name recognizes that the chromosomal structure of ancestral segments present due to admixture linkage disequilibrium (Figure 3) provides a basis for mapping genes with differential risk in ethnic/racial populations, even as the technique evolves and improves on an ongoing basis (Hoggart *et al*., 2004; Patterson *et al*., 2004;

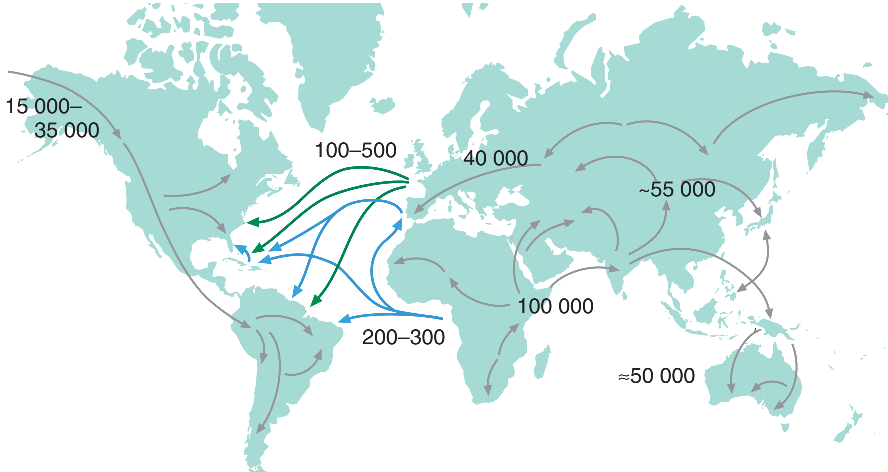

Figure 1 Migrations and diasporas of people that has led to admixed populations primarily in the Americas. (Adapted from several sources: Parra *et al*., 1998; Wiencke, 2004; Cavalli-Sforza and Feldman, 2003)

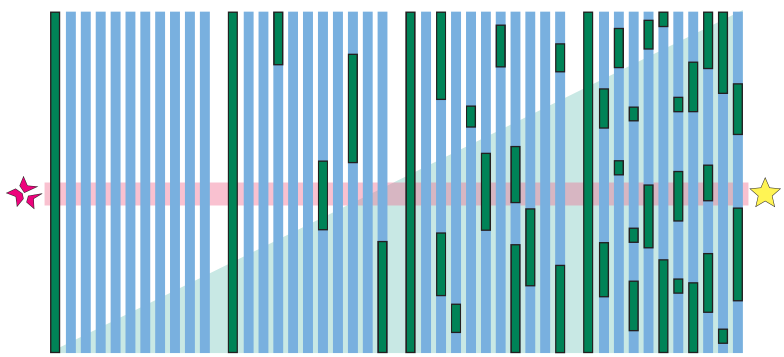

Figure 2 Schematic of chromosomes in the Admixed population with ancestry segments recombining as admixture takes place on an ongoing basis over time

Smith *et al*., 2004). The MALD technique actually only requires a difference in frequency of the various disease-causing variants and haplotypes (Hoggart *et al*., 2004; Patterson *et al*., 2004). An important analytical innovation is the proposed case-only design that uses the remainder of the genome and some individuals from the admixed population as the controls to discover disease genes utilizing the MALD approach (Hoggart *et al*., 2004; Montana and Pritchard, 2004; Patterson *et al*. 2004). The precision of the MALD gene mapping methodology to a few centimorgans (Patterson *et al*., 2004) falls between tens of cM for family studies (*see* Article 15, **Linkage mapping**, Volume 3) and significantly less than 1 cM for haplotype-map-based experimental designs covered elsewhere (*see* Article 12, **Haplotype mapping**, Volume 3 and Article 17, **Linkage disequilibrium and whole-genome association studies**, Volume 3). The intermediate discovery scale is addressed by the now practical method, MALD, for disease gene discovery

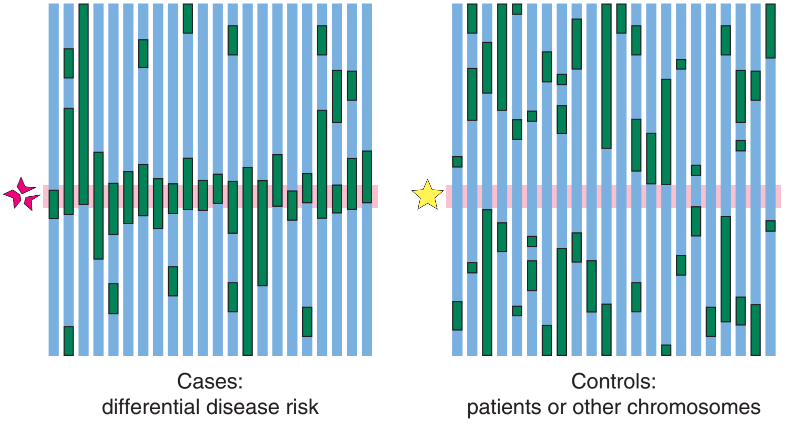

Figure 3 Schematic of experimental design to discover disease genes with differential prevalence in the green contributor to an admixed population

especially in African-Americans, where the necessary dense set of genome spanning markers was recently identified by Smith *et al*. (2004).

The identification of admixture as a novel property of some populations with application to gene identification and localization recognizes the possibility and known genetic mixing of the three major human population groups from Africa, Europe, or Asia (Briscoe *et al*., 1994; Chakraborty and Weiss, 1988; Stephens *et al*., 1994; McKeigue, 1997). Admixed groups include African-Americans, Hispanics, some Pacific Islanders, some South and Central Americans, and other groups of mixed origins (Halder and Shriver, 2003). The genetics of these admixed populations are rather complex as to their origins, timing of mixture, and dynamics have been addressed to a greater or lesser degree (Halder and Shriver, 2003). Utilizing MALD may be possible in all these admixed groups by genotying 10 000 to 15 000 random SNP markers (Montana and Pritchard, 2004), but parental population linkage disequilibrium between markers could prove problematic to this admixture map-less approach. The best understood case is of African-Americans, so this group provides a good starting point for explaining the basis and application of MALD in the real world.

In the African-American population of the United States, the proportion of admixture ranges from about 5 to 25%, depending on the population examined (Parra *et al*., 2001, 1998). In general, admixture is lowest in the southern United States like South Carolina (3–12%) and New Orleans (22%) along with Jamaica (7%), and highest in more northern cities like Pittsburg (25%), and Chicago (16%), Detroit (19%), Philadelphia (14%), New York city (19%) along with western cities like Los Angeles (26%) and Seattle (26%) (Wang, 2003). In parts of central America, a more complicated picture emerges. For instance, in the two populations from Santa Catarina Island in southern Brazil, contributions were estimated as African: 17% and 49%, European: 75% and 45%, and Amerindian 8% and 7% respectively (de Souza *et al*., 2003). Hispanics present a more heterogenous and less-studied picture of admixture with a population in the San Louis Valley of Colorado estimated as 63% European, 34% Native American, and 3% West African

(Bonilla *et al*., 2004). In contrast, Hispanics from California were assessed as 60% European and 40% Amerindian (Collins-Schramm *et al*., 2004). This particular study is consistent with a more general study that grouped Hispanics as Western or Eastern United States with Amerindian contributions of 36 to 58% or 0 to 21%, respectively, reflecting Mexican origins in the west and predominantly Cuban or Puerto Rican contributions in the East (Bertoni *et al*., 2003). Finally, admixture estimates from six Costa Rican populations show a great range in admixture for Europeans from 51 to 66%, Amerindians 27 to 35%, and Amerindians 7 to 14% (Morera *et al*., 2003). Levels of admixture also differ substantially between individuals (Smith *et al*., 2004; Parra *et al*., 2001, 1998). While the admixture levels differ substantially between populations and individuals, in general, the levels of admixture observed that falls between 10 and 90% are ideal for discovering genes that underlie genetic differences in diseases between source populations (Patterson *et al*., 2004).

Disease gene discovery is the reason for using MALD as an investigative tool while fully acknowledging the controversy of investigating the genetics of race and ethnicity (Risch *et al*., 2002; Schwartz, 2001). The merit of disregarding race relies on the fact that the majority of genetic variation is shared between groups, which, for example, predominates in interpretations of drug response (Wilson *et al*., 2001). Some reseachers have taken such simple observations in combination with the history of eugenics to suggest that race is best left alone and unstudied in genetics, while the benefits of examining race for understanding the genetics of disparities between racial groups is acknowledged by others (Risch *et al*., 2002; Schwartz, 2001; *Nature Genetics,* 2000). To that end, a group of diseases has been proposed for MALD-based gene discovery in African-Americans that includes hepatitis C clearance, melanoma, HIV vertical transmission, multiple sclerosis, suicide, HIV progression, lung cancer, stroke, end-stage renal disease, intracranial hemorrhage, focal segmental glomerulosclerosis, prostate cancer, hypertensive heart disease, and myeloma (Smith *et al*., 2004). Utilizing admixture to discover disease genes in admixed populations must be undertaken with caution, but is justified because of the potential benefit to the study subjects and their racial/ethnic group. Many studies are underway to test for genes that underlie these diseases in African-Americans and other groups (Halder and Shriver, 2003).

Discussion of the utilization of MALD to discover genes can be focused on the African-Americans, where the richest genetic resources are available and the nature of the admixture is best characterized. Basically, several requirements must be met to utilize admixture for disease gene discovery. One, the presence of large differences in allele frequencies at causative disease loci between founding populations is required. Since such differences in allele frequency at a disease locus are not knowable in practice, starting with diseases with very different prevalences in the two founding populations has to suffice as a substitute. Two, a set of well-spaced and highly differentiated genetic loci for examination of associations between disease status and chromosomal regions is needed and has been described recently (Smith *et al*., 2004). Three, analysis algorithms that can unravel the genetic complexities of real populations to discover genes must be developed and are becoming better as the ability to collect appropriate data has improved (Hoggart *et al*., 2004; Patterson *et al*., 2004). Finally, massively parallel and multiplexed

genotyping platforms are required to apply these markers to patient samples, and these have come along in their development of technologies for the international haplotype map project (Gibbs *et al*., 2003).

Recently, three papers on MALD were published back-to-back in the American Journal of Human Genetics (Hoggart *et al*., 2004; Patterson, 2004; Smith *et al*., 2004) and the accompanying description of the contents of the journal asked " . . . will it actually be able to find a disease gene?" Discovery of novel regions with disease genes will of course be the true test of the method. However, the validation of the importance of the Human Leukocyte Antigen (HLA) region in multiple sclerosis utilizing MALD analysis provides a promise for its future application (Oksenberg *et al*., 2004). Likewise, the ability to "find" genetic regions like the FY locus initially and many others recently illustrates the power of the technique (Patterson *et al*., 2004; Lautenberger *et al*., 2000). Regardless of these proofs of principle and the availability of a map, the efficacy of MALD will lie in its ability to point the way to discovery of novel disease genes important to human health.

MALD provides an exciting additional gene discovery methodology and tool that can complement both family studies and association approaches. It should be particularly effective in discovering disease with large differences in allele frequencies between racial groups. It should also be a good approach, when an environmental or viral factor is important as a causative agent in the disease process. Because MALD tracks genes through at most tens of generations, rather than the few of most family studies or the hundreds to thousands or more of associated ones, there may very well exist some effects for which MALD gives important insight by discovering genes that cannot be found otherwise. Application of MALD to ongoing disease genetics studies will test the ability of the technique to make robust novel disease genetics discoveries – currently, both the promise and bane of human genetic analysis.

Acknowledgments

I would like to thank Taras Oleksyk, Stephen J. O'Brien, David Reich, Nick Patterson David Altshuler, Josef Coresh, Michael Klag and Michael Dean for discussing important insights into MALD. This publication has been funded with Federal funds from the National Cancer Institute, National Institutes of Health, under Contract No. NO1-CO-12400. Short Specialist Review

Genotyping technology: the present and the future

Pui-Yan Kwok and Ting-Fung Chan
University of California, San Francisco, CA, USA

1. Introduction

The single nucleotide polymorphism (SNP), the most common form of genetic variation, has become the genetic marker of choice in the mapping of human traits (Schlotterer, 2004). An international consortium has been organized to harness the power of SNP markers and to construct high-density genetic and haplotype maps that will help us understand the genetic factors associated with many common diseases (Gilman *et al*., 2001; The IHC, 2003). Because of the tremendous technical challenge and demand for SNP genotyping, it has recently become the focus of considerable biotechnology entrepreneurship. Over the last decade, many approaches have been developed to reduce reagent and labor costs while improving accuracy, versatility, throughput, and simplicity of operation.

2. The present

Regardless of the principle behind the design, all genotyping methods consist of two stages: sample preparation and analysis. During the sample preparation step, different alleles of a particular SNP can be tagged either by a direct oligonucleotide-based hybridization method or by an enzyme-based method (such as ligation, primer extension, etc.) following probe hybridization. These methods are commonly known as allele-specific labeling (see Figure 1 for examples). As for detection, the product of the labeling reaction is analyzed by a variety of physical methods (such as direct fluorescence, fluorescence resonance energy transfer (FRET), fluorescence polarization (FP), or mass spectrometry, etc.). Many of these technologies have been extensively reviewed elsewhere (Gut, 2001; Syvänen, 2001) and are briefly summarized in Table 1.

3. Limitations

Even with all the genotyping technologies that are currently available, one cannot find a universal method that is suitable for all applications. This is due to the fact

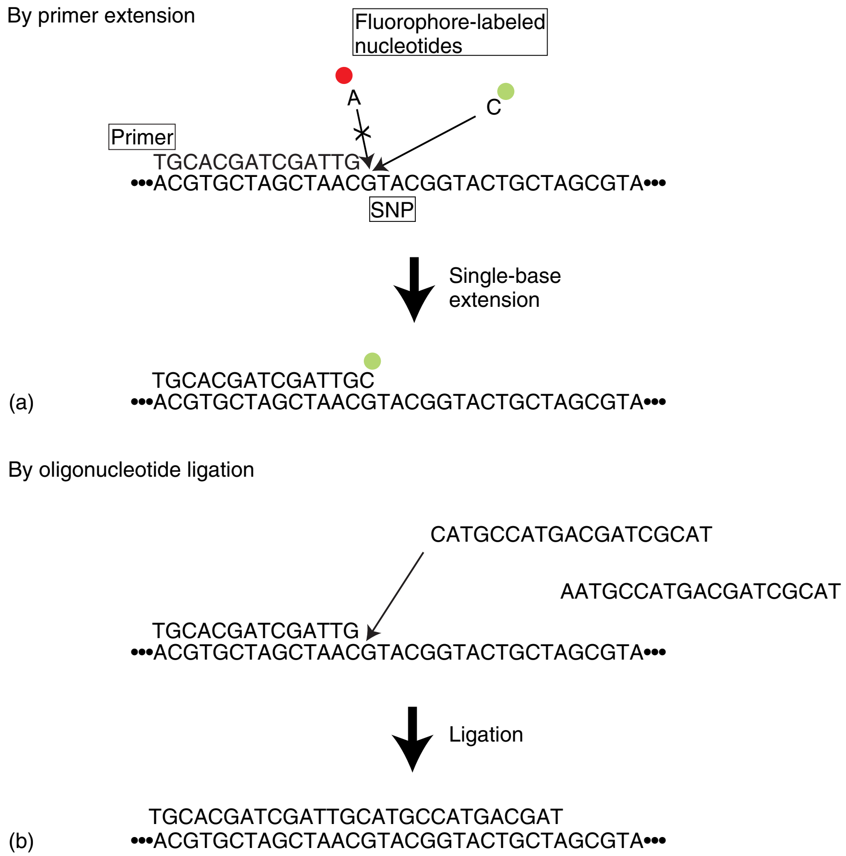

Figure 1 Examples of allele-specific labeling

that none of the current methods are completely versatile: some assays are simple to set up but are impossible to assay many SNPs simultaneously in multiplex reactions; others can be done in a highly multiplex format but require a long assay-development process and expensive, dedicated instruments. In general, the less multiplexed assays are easier to develop and failed assays can be optimized more easily. However, their operation cost is higher per genotype since the reactions are used to assay just one or a handful of SNPs. The highly multiplexed assays are much cheaper to perform once the "master mix" of probes is developed and validated. However, the "master mix" of probes cannot be changed even if it is desirable to do so when new SNPs need to be added to (or redundant SNPs removed from) the mix. Furthermore, any failed assays among the thousands of assays in the multiplex reaction cannot be "redone" since all the assays in multiplex must be assayed all over again. The choice of a technology is therefore heavily dependent on both the cost and the nature of the scientific question asked. Specifically, does a study need to genotype many individuals with a small number of SNPs; many SNPs in a small number of individuals; or many SNPs in many individuals?

Table 1 A selection of current genotyping technologies: examples of methodology

Sample preparation	Sample analysis	Method	Scale vs. flexibility
Hybridization	Fluorescence in array format	GeneChip microarray	High-throughput; low flexibility
	Fluorescence, FRET	Molecular beacons; TaqMan	Multiplex capable but probes are expensive
	Fluorescence	Dynamic allele-specific hybridization (DASH)	Complex probe design rules, high-throughput is possible
	Mass spectrometry	Peptide nucleic acids (PNA)	Multiplex capable but probes are expensive
Allele-specific PCR	Fluorescence, FRET	FRET primers	High-throughput and multiplex capable but primers are expensive; flexible
	FRET	AlphaScreen	High-throughput and multiplex capable but primers are expensive; flexible
Allele-specific primer extension	Chemiluminescence	Pyrosequencing	Difficult to multiplex; flexible
	Fluorescence polarization (FP)	Template-directed incorporation (TDI)	Difficult to multiplex; flexible
	Fluorescence in array format	Illumina coded microsphere	High-throughput; low flexibility
	Mass spectrometry	GOOD assay	Multistep procedure; flexible
Oligonucleotide ligation	Fluorescence in array format	Padlock probe/molecular inversion probe	Multiplex capable but probes are expensive
	Fluorescence	Ligation-rolling circle amplication (L-RCA)	Efficiency not known
Nuclease cleavage	Gel electrophoresis	Restriction site analysis	Not suitable for high throughput
	Mass spectrometry	Invader assay	Requires large amount of DNA, so throughput is questionable

4. The future

The primary concerns for the development of future genotyping technologies are cost, throughput, accuracy, simplicity, and versatility. An added concern is the "SNP content", meaning which sets of SNPs to use for particular studies. Until all the maps and most of the useful SNPs have been found and characterized, it is impossible to nail down a set of SNPs to develop assays around for all applications. In this article, we will therefore concentrate on the more technical issues.

With the emergence of nanotechnology and its interwoven relationships with biology, miniaturization is widely considered to be the next step in the evolution of genotyping technologies (Service, 2002). Microfluidics and microelectronics are the two main themes currently driving the progress to cheaper and faster assaying methods.

Microfluidics in biological assaying techniques can reduce cost significantly by reducing reaction volume, and hence the amount of reagents and enzymes needed for each reaction. Different steps of an assay can be performed in small-enough reaction volumes and be integrated into the so-called lab-on-a-chip format

to increase throughput. In principle, these lab-chip systems can be designed to be fully automated and operate in parallel, thereby reducing both reagent and labor costs, minimizing human errors at the same time (Liu *et al*., 2004; Mitchell, 2001). Microfluidics, however, is not without limitations. The number of genomic DNA copies in these small reaction volumes may be so low that allelic loss may result. Fluid flow obstructed by air bubbles or particulate matter can be a problem. Nonetheless, these problems did not hamper researchers' attempt to place SNP genotyping assay onto a microfluidic system (Russom *et al*., 2003). In time, this technology may mature to a point where routine operation is possible.

Applying microelectronic processes to genetic analysis is not an entirely recent concept. For example, photolithography using expensive chromium masks to fabricate oligonucleotide microarrays for high-throughput genotyping (Barone *et al*., 2001) is being replaced by a digital masking process (Nuwaysir *et al*., 2002), resulting in a faster and cheaper manufacturing process. Electric field microarray is another example of merging microelectronics with genotyping application (Gilles *et al*., 1999). Each microarray contains detection wells that are electronically programmable and can be configured and reconfigured for a particular SNP. An electric field is applied to concentrate the target DNA to the site where the probe is so that the time required for the hybridization process is greatly accelerated. Electronic stringency can also be adjusted at each detection well, which makes multiplexing possible as each SNP locus may require a different hybridization condition.

Microelectronic biosensors have also been developed for genetic analysis (Fritz *et al*., 2002). By the use of a field-electric sensor, which is based on an electrolyte-insulator-silicon (EIS) structure, any slight variation in surface potential by the presence of a charged molecule (i.e., nucleic acid) is detected by a change in conductivity. Because one is monitoring a change in the physical property of the DNA molecules, the need for fluorescent or other labels is eliminated. Although it is still at an early stage of development, the sensor accurately detects single-base mismatches during nucleic acid hybridization. Since as many as a million of such sensor spots can be packed onto a single chip, this is a promising genotyping platform in the future (Uslu *et al*., 2004).

Developing an affordable genotyping platform that is fast and accurate, simple and yet versatile requires continuous research advancement in genomics, nanotechnology, material sciences, and computer technology. This will happen only when people from different areas of expertise – biology, chemistry, physics, mathematics, and engineering – collaborate to tackle the problem. With rapid progress in genome-sequencing technologies during the past decade as precedent, the next wave of breakthroughs in genotyping technology will surely benefit from the age of integrated biology.

Introductory Review

What is an EST?

Winston A. Hide

South African National Bioinformatics Institute, University of the Western Cape, Bellville, South Africa

Andrey Ptitsyn

Pennington Biomedical Research Center, Baton Rouge, LA, USA

1. History of EST development

Technology for the high-throughput capture of DNA sequence was developed in the 1980s and early 1990s (*see* Article 24, **The Human Genome Project**, Volume 3) in preparation for the human genome project. The ability to find genes in genome sequences was limited and dependent upon the arduous task of sequencing a genome fragment. Sequencing technology is constrained to a relatively short read length. Therefore, strategies for sequencing large genome fragments rely upon breaking them up into little pieces. The task involves making a "library" of genomic sequences in a random manner, termed a shotgun library. The fragments in the library are inserted into a sequencing vector and are subsequently sequenced (*see* Article 4, **Sequencing templates – shotgun clone isolation versus amplification approaches**, Volume 3). Each fragment insert is within a size range that allows for a number of such sequence fragments to completely overlap each other and form an alignment or "assembly". The resulting contig that is generated is overlapped with other contigs to make up a genome fragment. The process is expensive and labor intensive, and finding genes within the genome sequence is not an exact science, resulting in a significant challenge (*see* Article 14, **Eukaryotic gene finding**, Volume 7).

Together with his team led by Mark Adams, Craig Venter exploited the shotgun sequencing technology already available to sequence cDNAs instead of shotgun genome fragments. Rather than attempting to sequence complete cDNAs to yield a few hundred gene sequences, Venter's group took a radical step: they made thousands of cDNAs from an mRNA library and simply inserted them into a sequencing vector. Instead of attempting to sequence a handful of full-length cDNAs, they performed shotgun style sequencing on the large collection of cDNAs. The single read sequences that resulted were essentially expressed gene tags. At around the same time as the development of ESTs (expressed sequence tags), drug companies were assessing their drug discovery approaches. George Poste at Smith-Kline was one of the first to recognize the potential of high-throughput information and together with Craig Venter and William Haseltine helped set up genomic

facilities such as Human Genome Sciences (a for profit company) and the Institute for Genome Research (a not-for-profit organization). The result was an immediate development of extensive proprietary EST data collections, and the race to discover all genes in the human genome began. The high-profile actions of Smith-Kline attracted intense competition amongst EST manufacturing centers and companies alike (Marshall, 1996). Entering late into the genomic competition, Merck took a risky strategy of funding "dumping" of ESTs into the public domain, probably in an attempt to reduce the proprietary value of EST tags in the possession of their competitor, Smith-Kline. The resulting database growth provided the foundation upon which modern bioinformatics has developed. 3 618 403 ESTs were present in dbEST, the most well known repository of ESTs, as of October 2004.

Each EST represents only a tiny portion of an entire transcribed gene fragment. Initially, ESTs were intended to merely identify the expressed gene. Mark Adams first published the approach for making ESTs in a widely read article in 1991 (Adams *et al*., 1991). The process by which ESTs are manufactured requires the construction of an mRNA library. Baldo *et al*. (1996) have provided a detailed description of how libraries are constructed and how normalization and library subtraction can be used to increase relative representation of less abundantly transcribed mRNAs. An average size of EST libraries ranges typically from 1000 to 10 000 entries (clones). It is estimated that from 10 to 30 000 different genes are expressed in a particular cell, depending on the cell type, with an average number of approximately 300 000 mRNA molecules per cell. The real number of different transcripts, resulting from alternative splicing, alternative polyadenylation, and posttranscriptional modification is yet to be discovered, but it can be estimated that the number of different transcripts far exceeds the number of genes in genome. Thus, an EST library cannot be regarded as a proper representation of the gene-expression pattern of a tissue (Vingron and Hoheisel, 1999). An EST library only represents a coarse-grained snapshot of the mRNA contents of a certain tissue at a certain moment. Low-expression genes are always underrepresented. As a rich source of discovery, EST libraries immediately attracted the attention of many scientists. During the last decade, hundreds of research projects have employed EST data in some form, either as primary data or as a supplementary source of information.

In order to understand EST sequence information, it is important to understand the means of EST manufacture. ESTs begin with the isolation of mRNAs from the collected biological samples. Each mRNA is then reverse-transcribed into a cDNA. The reverse transcriptase used to manufacture each cDNA in the library will eventually fall off the template (Figure 1), and so will terminate the production of the cDNA. Thus, a series of length-differentiated 3′ delimited cDNA fragments may be produced for each viable template mRNA in the library. The length of the cDNA will vary, and this is an important factor for the development of coverage for each mRNA template of an available gene. Clones are sequenced one at a time, from one or both ends of the DNA insert, using universal primers, which are complementary to the vector at the multiple cloning sites. The M13 forward primer may be located near the 5′ or the 3′ end of the cloned insert, depending on how the inserts were directionally cloned. Consequently, untranslated regions on the ends of the genes tend to be overrepresented by sequence tags. Only a few

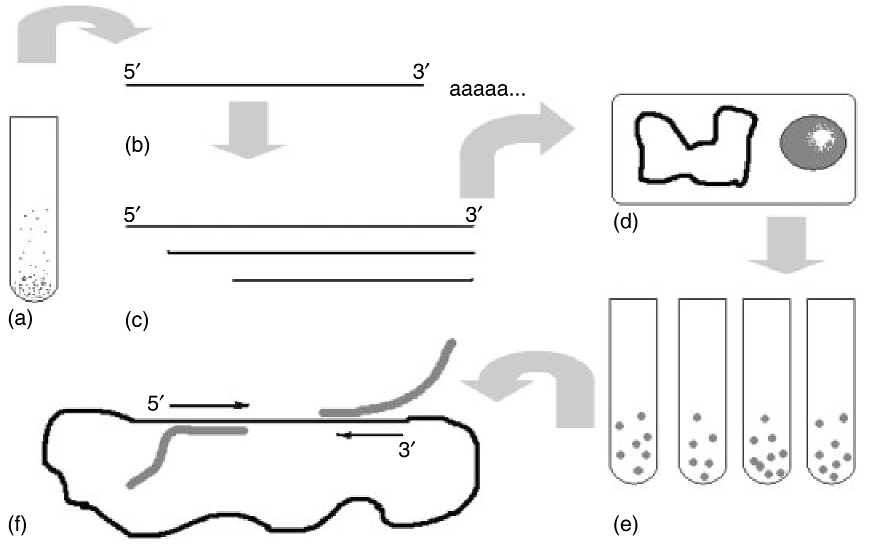

Figure 1 View of an EST manufacture process. After a sample (a) is collected, all transcribed copies of expressed genes (mRNAs) are isolated (b). Each mRNA is reverse-transcribed into a complementary DNA (cDNA) (c). Note that cDNA copies may have different lengths due to the polymerase processivity. The copy number of fragments is increased when they are inserted into a host cell (d). The resulting population of host cells containing cDNA fragments from the sample of interest is called a cDNA library (e). Typically, a few thousand clones are randomly picked from the cDNA library to produce single-pass 3′ reads, sometimes from the 5′ ends, and sometimes from a random location (f). The resulting collection represents fragments of different lengths starting from the polyadenylation site at 3′ end and partially overlapping fragments from 5′ end. Although 3′ and 5′ ESTs rarely overlap, they usually share the same clone ID in the annotation

hundred readable bases are produced from each sequencing read, and yet a full gene transcript may be several thousands of bases long. In publicly available databases, EST length varies from less than 20 to over 7000 bp, with an average length of 360 bp and standard deviation of 120 bp (dbEST, Genbank rel. 104). Not all are true single-read tags, but they are submitted and accepted as such, bringing extra complications to the EST database analysis. There are also countless variations in the EST generation technique. One of the most significant is using random primers, which results in production of fragments without direction, originating from different nonoverlapping parts of the same mRNA (Kapros *et al*., 1994). ESTs thus provide a "tag level" association with an expressed gene sequence, trading quality, and total sequence length for the high quantity of genes partially captured.

EST data quality varies greatly. Generation of EST data results in "low quality" sequence information. A single read is generated for each EST, and as such will contain errors from its generation at each step. These can include clone orientation, associated clone ID chimeras, and missing 3′ and 5′ reads. Because data are single-pass unedited sequences, they are also subject to errors caused by compressions and base-calling problems resulting in frame shifts. Reference to the Washington University website details common aspects of EST error (**http://genome.wustl.edu/est/**

and **http://genome.wustl.edu/est/index.php?std=1&disclaimer=1**). EST sequence has regions of high quality very close to regions of low quality, where quality can be defined as the number of correctly sequenced bases within a known window of reference. It is possible to utilize poor-quality sequence as long as relevant strategies for maximizing their utility are taken.

Introductory Review

Technologies for systematic analysis of eukaryotic transcriptomes

Robert L. Strausberg
The J. Craig Venter Institute, Rockville, MD, USA

1. Introduction

While much attention during the previous decade was focused on sequencing the genomes of the human (Venter, 2001; Lander, 2001) and other organisms, a revolution was already underway in identifying the coding content of these genomes. Complementary to genomic approaches, advances in transcriptome and proteome technologies provide an unprecedented opportunity to probe the diversity of gene expression and related biological functions. While much attention has been directed to the perceived limited number of human genes compared with previous expectations (Venter, 2001; Collins *et al*., 2004), it has become clear that eukaryotic transcript diversity is indeed very high (Xu and Lee, 2003; Wang *et al*., 2003b; Kapranov, 2002; Kriventseva *et al*., 2003; Hide *et al*., 2001). Indeed, alternative transcription and transcript processing provides new opportunity for discovery, as well as challenges to transcriptome technologies. Discussed in this overview are transcriptome-based technologies based on serial sequencing and hybridization that provide new opportunities for discovery and/or comprehensive high-throughput analysis.

2. Serial sequencing-based transcriptome technologies

The complexity of eukaryotic gene structure provides much opportunity for the generation of a diversity of transcripts from each gene. As shown in Figure 1, alternative transcripts can be generated through the use of alternative promoters, differential exon splicing, as well as the use of alternative polyadenylation sites (Kriventseva *et al*., 2003). Numerous studies have demonstrated that while some alternative transcript processing might reflect biological “noise”, many alternative processing events are correlated with changes in biological function (Xu and Lee, 2003; Yi, 2000; Munro *et al*., 1999).

While presenting an opportunity for discovery, the diversity of transcripts also presents technological challenges. First, transcripts are produced at very different

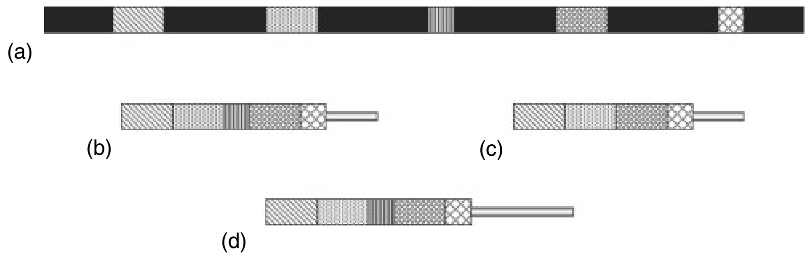

Figure 1 Multiple transcripts from individual genes. The diversity of eukaryotic transcripts is greatly enriched by the production of alternative transcripts from individual genes. For example, the 5′ or 3′ end of the transcripts can be extended by the use of alternative promoters and differential use of polyadenylation sites, respectively. In addition, alternative splicing can result in transcripts with differences in exon content. Illustrative of this phenomenon are three transcripts derived from the hypothetical gene A in which the black bars represent introns and the alternatively filled bars represent exons. Transcript B has a complete complement of the five exons. Transcript C is lacking the third exon and transcript D has an extended 3′ end based on the use of an alternative polyadenylation site

levels in cells, with some expressed only very rarely (Holland, 2002). In addition, transcripts vary greatly in size, with many being more than several thousand nucleotides. Thus, while it is the ultimate goal of transcript biology to gain complete knowledge of transcript diversity, there is no currently available technological approach that fulfills this need. However, through a combination of technological approaches, a more complete knowledge of eukaryotic transcripts is being gleaned, and applied to biomedical research.

3. cDNA libraries and sequencing

At the center of the transcript discovery and categorization are full-length cDNA (Ota, 2004; Imanishi, 2004; Strausberg *et al*., 2002a; Beisel, 2004; Okazaki, 2002) and expressed sequence tag (EST) (Adams, 1991; Brentani, 2003; Riggins and Strausberg, 2001; Scanlan, 2002; Sonstegard, 2002; Strausberg *et al*., 2002; Strausberg *et al*., 2002b; Strausberg and Riggins, 2001; Strausberg *et al*., 2003) efforts. In these approaches, cDNA libraries are prepared starting with mRNA derived from cell lines or tissues, and the cDNAs are single-pass sequenced, usually from the 5′ or 3′ ends (ESTs), or completely. In a novel EST strategy, called ORESTES, a random priming approach is used to generate EST sequences that are derived more frequently from the central coding region of the transcript (Strausberg *et al*., 2002b; Sakabe *et al*., 2003; de Souza, 2000).

Preparation of cDNA libraries can be based on a variety of technological approaches. In part because mRNAs are particularly fragile, the preparation of libraries that are enriched for full-length cDNAs is very challenging. In standard cDNA libraries, the frequency of each cDNA approximately reflects the relative proportion of each type of mRNA in the cell or tissue. Special approaches such as CAP-trapping are employed to capture the 5′ end of the mRNA, thereby enriching for full-length cDNAs (Hirozane-Kishikawa, 2003). Specialized library

normalization strategies (Bonaldo *et al*., 1996) are used to make the relative proportion of each cDNA in the library approximately equal, irrespective of the original differences in transcript proportions. Subtraction technologies (Hirozane-Kishikawa, 2003; Bonaldo *et al*., 1996) are employed to enhance the proportion of certain cDNAs in the library, such as those that have not previously been sampled. Normalization and subtraction are very important for the identification of cDNAs derived from transcripts that are infrequently expressed. These cDNA approaches have been critical for gene discovery, for defining the structure of genes in the human and other genomes, and for identifying alternative transcript processing. In addition to the valuable sequence information, physical collections of cDNAs have been made accessible to the community (Imanishi, 2004; Strausberg *et al*., 2002a,b; Kawai, 2001; Tanaka, 2000; Klein, 2002; Lennon *et al*., 1996; Sharov, 2003). Therefore, they serve as an important platform for all gene expression approaches.

4. Transcript tagging strategies

Although a long-term goal of transcriptome research is to catalog all of the transcript sequences in a cell, as well as to understand variations within networks, at present such an approach is too expensive. Therefore, clever strategies have been employed that allow for surveys of genes that are expressed in various cells. For example, although based on very different technological platforms, both the Serial Analysis of Gene Expression (SAGE) (Weeraratna, 2004; Porter *et al*., 2003; Porter and Polyak, 2003; Fujii, 2002; Velculescu *et al*., 1995; Boon, 2002; Lash, 2000; Velculescu *et al*., 2000; Lal, 1999) and Massively Parallel Signature Sequencing (MPSS) (Brandenberger, 2004; Meyers, 2004; Jongeneel, 2003; Brenner, 2000) provide short sequence tags, generally up to about 20 nucleotides, derived from the 3′ end of transcripts. The SAGE approach has now been employed for a decade and gained popularity because it is quantitative and provides data that is digital (DNA sequence) and is relatively cost-effective for tag generation compared to the cDNA approach because in SAGE the tags are concatenated, and 30 or more gene tags can be derived from each sequencing read. In addition, the digital nature of SAGE data facilitates the development of databases accessible to the community (Boon, 2002; Lash, 2000; Lal, 1999). The MPSS approach is based on a non-gel-based sequencing, together with in vitro cloning of templates on microbeads. MPSS has the advantage of generating several million tags per sample. This is particularly useful in that it extends the proportion of all transcripts that can be identified reliably within a sample (Brandenberger, 2004; Meyers, 2004; Jongeneel, 2003). Both technologies are somewhat limited by their inability to tag a small subset of transcripts because the cDNA lacks the specific restriction site required for tag generation, and because a certain fraction of tags do not uniquely identify the gene from which a transcript is derived.

The SAGE and MPSS approaches have both been employed effectively for identifying genes that are overexpressed in various tissues (for example, tumors compared with their normal counterparts) for biomarker applications, as well as potential targets for therapeutic intervention (Weeraratna, 2004; Porter *et al*., 2003;

Porter and Polyak, 2003; Fujii, 2002; Iacobuzio-Donahue *et al.*, 2003). The application of clever front-end strategies for preparation of specialized samples, together with novel approaches for database mining, has revealed genes that are specifically expressed in very specialized cell populations, such as in tumor-associated endothelium (St Croix, 2000).

5. Microarray-based strategies

Complementing the sequence-based approaches are those based on hybridization technology, using oligonucleotides (Lipshutz *et al.*, 1999; Wang *et al.*, 2003a) or cDNAs (Lapointe, 2004; Murray, 2004; Sorlie, 2003; Chen, 2003; Cheng, 2003; Ramaswamy and Perou, 2003; Alizadeh *et al.*, 2001) as probes to assess the presence and relative amounts of transcripts in cells and tissues. As the density of these chip formats has improved, and the knowledge of transcribed sequences has increased, expression of the complement of the genes in a genome, including the human, can be studied en masse. The high-throughput nature of this approach is a substantial advantage, as is the ability to study the entirety of transcript populations, limited in principle only by the DNA probes displayed on the chip. In cDNA formats, expression of each gene is, in general, assayed compared with an RNA reference, and results for each gene are characterized by the relative level of over- or underexpression (Sorlie, 2003; Chen, 2003; Bohen, 2003; Novoradovskaya, 2003). In the oligonucleotide format of Affymetrix, measurements are made on individual samples, thereby providing a quantitative view of gene expression (Lipshutz *et al.*, 1999). Array technologies have been applied to study a diversity of biological processes and diseases. For example, in cancer research, these technologies have been applied extensively toward molecular classification of tumors (Sorlie, 2003; Ramaswamy and Perou, 2003; Bloom, 2004; Chen, 2002; Chung *et al.*, 2002; Golub, 1999; Grant, 2004; Ramaswamy *et al.*, 2001; Wong, 2003; Ha, 2003; van't Veer, 2002; Perou, 1999).

The choice of probes must be carefully considered to achieve adequate specificity and informativeness. For example, transcripts from related genes may hybridize the same probes. In most cases, oligonucleotide probes have been targeted to the 3′ transcript end. However, recent advances in labeling strategies and chip design have opened opportunities to measure the full complement of transcripts (Yeakley, 2002). In addition, recent efforts to span entire chromosomes and genomes with oligonucleotide probes have facilitated de novo identification of transcripts (Kapranov, 2002).

6. Comparing the output of various gene expression technologies

A number of studies have compared the relative strengths and limitations of transcriptome technologies (Weeraratna, 2004; Bloom, 2004; Yauk *et al.*, 2004; Czechowski *et al.*, 2004; Lu *et al.*, 2004; Kim, 2003; Ye *et al.*, 2002; Toyoda,

2003; Coughlan *et al*., 2004). In general, the results have revealed that the measured expression levels for genes that are produced at moderate to high levels are at least qualitatively similar. However, as mentioned, transcripts are expressed at widely divergent levels, and for those that are produced in very limited quantities, the technologies produce quite different results. In a systematic study of *Arabidopsis* transcription factors by real-time RT-PCR, transcript abundance ranged between 0.001 and 100 copies per cell (Czechowski *et al*., 2004). However, only about half of these genes were detected on oligonucleotide arrays, and many of the transcripts were not present in the EST and MPSS databases. Genes expressed at low levels were especially underrepresented in these databases. This study demonstrates the need to carefully consider the dynamic range of the technology that is utilized.

In general, it is important to verify expression results derived from one technological approach with additional technologies. For example, genes that are measured to be differentially expressed by SAGE technology are often verified through the use of RT-PCR (Weeraratna, 2004; Porter *et al*., 2003; Loging, 2000). In addition, technologies such as tissue microarrays (Bloom, 2004; Mobasheri *et al*., 2004; Hans, 2004; Swierczynski, 2004; Jacquemier, 2003; Kallioniemi *et al*., 2001) offer the opportunity to examine a larger number of biological samples, and to gain perspective on expression and localization of protein derived from specific transcripts. Moreover, additional information can be gleaned by comparing expression data with genomic changes, such as gene copy number alterations (Hyman, 2002; Pollack, 2002).

7. Accessing transcriptome datasets

A variety of Internet-accessible databases (Strausberg *et al*., 2003; Boon, 2002; Lash, 2000; Lal, 1999; Pospisil *et al*., 2002; Ringwald, 2001) are available to facilitate the use of transcriptome data and for integration with additional datasets. For example, the National Center for Biotechnology Information's Gene Expression Omnibus (**http://www.ncbi.nlm.nih.gov/geo/**) displays both microarray and SAGE data submitted by the community. Genome browsers, such as the one developed and maintained at the University of California Santa Cruz (**http://genome.ucsc.edu/**), display a wide variety of transcriptome data, integrated with the human genome sequence and known genetic variation. Other resources, especially the NCI Cancer Genome Anatomy Project (**http://cgap.nci.nih.gov**), display a wealth of cancer-related transcriptome data, integrated with other datasets of interest to the community such as the Mitelman database of chromosome aberrations, as well as genetic variation in cancer-related genes. Together, these and other Web-based sites offer a wealth of data for online viewing and in silico experimentation.

8. Summary

Comprehensive transcriptome technologies offer an unprecedented opportunity to view the interplay of genes and networks within cells and tissues. While each of the technologies is somewhat limited, together they are a powerful new resource for

biological and biomedical research. Continued progress in technology development is required to completely characterize eukaryotic transcriptomes, especially with respect to transcripts that are rarely expressed. The study of alternative splice forms will likely provide much insight to the diversity of biological states. Overall, the progress over the past decade is quite remarkable and sets the stage for future research in which transcriptomes will truly be amenable to comprehensive study.

Specialist Review

EST resources, clone sets, and databases

Janet F. Kelso
University of the Western Cape, Bellville, South Africa

1. Introduction

Gene identification via complete or partial transcript capture has proved to be a valuable and rapid route to gene discovery (Boguski and Schuler, 1995; Schuler *et al.*, 1996). The sequencing of Expressed Sequence Tags (ESTs) has been used in numerous pilot gene identification projects in which it has provided insight into the transcribed genomes of a wide range of organisms.

As a result, many groups, both academic and commercial, have contributed and continue to deposit many thousands of ESTs representing numerous organisms and expression states to public databases. In addition, many also distribute publicly the source clone sets from which these ESTs were generated, providing an experimental resource for expression studies.

2. EST databases

The public EST databases can be divided into (1) those that perform no processing of the incoming data and simply act as data repositories and (2) those that preprocess the data to reduce error and take advantage of sequence redundancy to increase quality.

2.1. Unprocessed EST databases

2.1.1. dbEST http://www.ncbi.nlm.nih.gov/dbEST/

dbEST, the EST division of Genbank, is a public repository for raw EST sequence and annotation information (Boguski *et al.*, 1993; Boguski and Schuler, 1995). More than 20 million ESTs representing in excess of 650 organisms have been deposited in dbEST since its inception in 1991. The most organisms most highly represented in dbEST are listed in Table 1. This EST data is available by anonymous

Table 1 Top 10 organisms represented in dbEST (26 February 2004)

Organism	ESTs
Homo sapiens (human)	5 472 005
Mus musculus + *domesticus* (mouse)	4 056 481
Rattus sp. (rat)	583 841
Triticum aestivum (wheat)	549 926
Ciona intestinalis	492 511
Gallus gallus (chicken)	460 385
Danio rerio (zebrafish)	450 652
Zea mays (maize)	391 417
Xenopus laevis (African clawed frog)	359 901
Hordeum vulgare + subsp. *vulgare* (barley)	352 924

ftp from **ftp://ncbi.nlm.nih.gov/genbank/**. Individual sequences and small batches can be obtained using Entrez (**http://www.ncbi.nlm.nih.gov/entrez/**).

The highly redundant EST data in dbEST is not clustered or assembled, and only a subset is grouped by species of origin. Unrestricted homology searches against dbEST will therefore commonly return numerous sequences that represent the same gene as the query, paralogous genes, and sequences from related species. Both the National Center for Biotechnology Information (NCBI) (**http://www.ncbi.nlm.nih.gov/BLAST/**) and the Swiss Institute of Bioinformatics (SIB) (**http://www.ch.embnet.org/software/aBLAST.html**) offer the ability to search subsets of dbEST restricted by species, with NCBI offering human, mouse, and "other" divisions and SIB offering the ability to select one or more from a large number of divisions including plants, prokaryotes, fungi, invertebrates, zebrafish, human, mouse, and rat.

2.2. *Processed EST databases*

EST data can be organized and presented in such a way as to produce valuable information about gene expression, including details of the location and timing of transcript expression, alternative splicing, and regulation. In general, the data stored in the large public EST databases is largely unorganized, sparsely annotated, and redundant. The sequences themselves are usually short, unprocessed, and error-prone.

However, the sheer volume of EST data generated by large-scale EST sequencing projects means that a significant improvement in reliability can be gained by taking advantage of EST sequence redundancy to reduce error and increase the length of represented transcripts (Jongeneel, 2000).

EST clustering systems that preprocess, cluster, and postprocess EST data to yield higher-quality transcript information aim to construct gene indices; nonredundant catalogs in which all represented transcripts are partitioned into groups (clusters) such that transcripts are placed in the same cluster if they represent the same gene or gene isoform. Gene indices facilitate gene expression studies and novel transcript detection. In addition to clustering, many groups perform

transcript reconstruction, using assembled clusters to build a consensus sequence that provides a longer and more accurate representation of the transcript represented by the cluster.

Homology searching against clustered EST collections such as Unigene will result in a more concise report than searching dbEST. Homology searching against clustered databases that provide contigs and consensus sequences for each cluster is very rapid, though the accuracy of the contig production and consensus sequence generation may affect the quality of the matches obtained.

A number of gene indices have been produced using publicly available EST data. These aim to reduce the error and redundancy present in the raw data and to thereby enhance the useful transcript information that can be gleaned from ESTs. The Institute for Genome Research (TIGR) gene indices (Quackenbush *et al*., 2000; Quackenbush *et al*., 2001) and Unigene (Wheeler *et al*., 2003), produced by NCBI, have focused on providing a reconstruction of the gene complement of various genomes. The STACK database (Christoffels *et al*., 2001; Miller *et al*., 1999) has focused on the detection and visualization of transcript variation and the production of accurate consensus sequences that represent the transcript variation in the context of tissue, developmental stage, and pathological states.

Both the TIGR and STACK databases offer BLASTable gene indices on their respective websites.

2.2.1. Unigene http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=unigene

Unigene, based at the National Centre for Biotechnology Information (NCBI), is one of the earliest and most enduring efforts for the automatic production of gene indices from Genbank sequences. Each Unigene cluster contains mRNA and EST sequences that represent a unique gene. Additional information such as the identity of the gene, chromosomal map location, and tissue types in which the gene is expressed (from SAGE and EST data) is also provided. NCBI does not generate contigs and/or consensus sequences for Unigene clusters.

Unigene databases are available for 38 organisms including: human (*Homo sapiens*), mouse (*Mus musculus*), rat (*Rattus norvegicus*), zebrafish (*Danio rerio*), Cow (*Bos taurus*), Clawed frog (*Xenopus laevis*), Arabidopsis (*Arabidopsis thaliana*), wheat (*Triticum aestivum*), rice (*Oryza sativa*), barley (*Hordeum vulgare*), and maize (*Zea mays*). Databases are updated weekly with new ESTs and bimonthly with newly characterized sequences. All Unigene databases are available for download from **ftp://ncbi.nlm.nih.gov/repository/UniGene/**.

Unigene clusters can be searched by gene name, Unigene cluster ID, chromosomal location, cDNA library, accession number, and text terms. Sequence-based searches against Unigene human, rat, and mouse databases are available from the SIB at **http://www.ch.embnet.org/**.

Unigene has been used for the selection of unique transcripts for the construction of a cDNA microarray for the large-scale analysis of gene expression and as the candidates for the production of a human gene map.

For information on the construction of Unigene, see **http://www.ncbi.nlm.nih.gov/UniGene/build.html**.

2.2.2. TIGR Gene Indices http://www.tigr.org/tdb/tgi.shtml

TIGR produces gene indices for more than 40 organisms including various animal, plant, protist, and fungal species (Quackenbush *et al*., 2001; Quackenbush *et al*., 2000). The TIGR indices incorporate both ESTs sequenced at TIGR, ESTs from dbEST, and mRNAs from Genbank. Each TIGR cluster is represented by a Tentative Consensus sequence (TC, or THC in the case of Tentative Human Consensi), which is a FASTA-formatted sequence with a unique accession as well as additional information including details of the assembly, putative gene identification, and a list of tissues in which the transcript is expressed. Related databases generated by TIGR provide additional information about TCs. The Genomic Maps database provides genomic mapping for a subset of organisms for which TCs are available. The Institute for Genome Research Orthologous Gene Alignment database (TOGA) (Lee *et al*., 2002) provides information about orthologous sequences between TCs for the organisms for which TIGR gene indices have been generated.

The TIGR databases are freely available to researchers at nonprofit organizations at **http://www.tigr.org/tdb/tgi.shtml**. The TIGR Human Gene Index (HGI) is produced annually. The frequency of new releases varies between species and depends on the accumulation of new transcripts. The TIGR gene indices can be searched by nucleotide or protein sequence, EST, transcript or consensus identifiers, tissue, cDNA library name or library identifier, gene product name, or functional classification according to Gene Ontology (GO) terms (Ashburner *et al*., 2000).

2.2.3. STACK http://www.sanbi.ac.za/Dbases.html

The STACK human gene index is generated by clustering EST and mRNA data, and offers human transcript consensus sequences that reflect gene expression forms and alternate expression variants within 15 tissue-based and one disease category (Christoffels *et al*., 2001; Miller *et al*., 1999). This organization of transcript by expression site presents the opportunity to explore transcript expression in specific tissues or subsets such as disease-related sequences.

Each STACK cluster contains alignments, consensus sequences, and assembly information, and is dynamically linked to the Unigene database. Web-based software allows for the visualization of clusters and alignments, and highlights transcript variation. STACK database releases are made available with varying frequency – on average twice a year. STACKdb and the stackPACK toolset used to generate STACK are freely available to academic groups and can be downloaded from **http://www.sanbi.ac.za/CODES**. Sequence-based searching of STACKdb tissue divisions is available at **http://juju.egenetics.com/cgi-bin/stackpack/blast.py**.

STACKdb has been used to support the detection of a novel retinal-specific gene responsible for retinitis pigmentosa. The STACKpack toolset has been used in the production of various gene indices and for the survey of genes in the malarial genome.

2.3. cDNA clone sets

The availability of clones representing partial or full-length transcripts in an organized public collection is a critical resource for the ongoing genomic research. Clone sets have applications in gene discovery, a range of functional genetic analyses, and also as substrates for microarray expression studies.

2.3.1. I.M.A.G.E http://image.llnl.gov/

Recognizing the need for a publicly available clone collection, the Integrated Molecular Analysis of Genomes and their Expression (I.M.A.G.E.) consortium was formed in 1993. The aim of the group was to make cDNA clones representing all known genes, as well as their sequence, map, and expression information, publically available in order to facilitate biological research (Lennon *et al*., 1996). To this end, the group has generated more than 7.5 million clones from over 882 cDNA libraries representing more than 50 human tissues, as well as mouse, rat, zebrafish, rhesus monkey, *Fugu*, and *Xenopus*.

EST projects that are part of the I.M.A.G.E. consortium are listed in Table 2.

The sequences from the I.M.A.G.E. clones are submitted to dbEST, and the clones themselves are generally available royalty-free through a network of distributors in the United States and Europe (**http://image.llnl.gov/image/html/idistributors.shtml**). These groups generally provide added services that allow users to select the most appropriate clones for their research. I.M.A.G.E consortium distributors in Europe and the USA are listed in Table 3.

The I.M.A.G.E. consortium uses and provides IMAGEne, a clustering toolset to cluster the sequences from I.M.A.G.E. cDNA clones (Cariaso *et al*., 1999). Known gene clusters are based on NCBI's RefSeq, and candidate gene clusters are those with no known gene association. Those clones whose sequences do not match any other cDNA are grouped as Singletons. Users of the system are able to query against these cluster sets to obtain a list of available I.M.A.G.E. clones aligned with the corresponding known gene or consensus sequence. By offering the best representative clones that are available for order from the I.M.A.G.E clone set, IMAGEne provides a valuable laboratory research tool. IMAGEne is available via the web at **http://image.llnl.gov/image/imagene/current/bin/search**.

3. Conclusion

The EST databases provide an invaluable view of the transcriptomes of a large and growing number of organisms. The availability of EST data, and the associated annotation information, including details of the tissue source, provides an early expression map of the transcriptomes for these organisms. The public availability of clone sets representing a large number of organisms, tissues, diseases, and developmental stages is a valuable and ongoing resource for expression profiling and functional genomics studies.

Table 2 Some of the major I.M.A.G.E consortium EST projects

Project	Date	URL	Description
Merck/WashU EST Project	1995–1997	**http://genome.wustl.edu/est/index.php?human_merck=1**	A major early contribution to dbEST was the sequencing of 584 000 ESTs by Washington University under a project launched by Merck and Co. The cDNA libraries were constructed by Bento Soares at Columbia University, and arraying for high-throughput processing was performed by Greg Lennon at the Lawrence Livermore National Laboratory (Boguski and Schuler, 1995).
HHMI/WashU Mouse EST Project	1996–1998	**http://genome.wustl.edu/est/index.php?mouse=1**	Approximately, 400 000 mouse ESTs were contributed to dbEST by Washington University under the sponsorship of the Howard Hughes Medical Institute.
Cancer Genome Anatomy Project (CGAP)	1997–(ongoing)	**http://cgap.nci.nih.gov**	Through funding from the National Cancer Institute (NCI), human clones, largely from NCI-CGAP and ORESTES libraries, have been sequenced by Washington University and The NIH Intramural Sequencing Center (NISC). The aim of CGAP is to determine the gene expression profiles of normal, precancer, and cancer cells with a view to improving cancer diagnosis and treatment. Since 1999, CGAP has also contributed libraries and sequences for mouse, rat, Xenopus, and primate.
WashU Zebrafish EST Project	1997–2002	**http://genome.wustl.edu/est/index.php?zebrafish=1**	cDNA libraries produced by the zebrafish research community prior to 2002 have been arrayed by the I.M.A.G.E. consortium and sequenced at Washington University.
NIH Zebrafish Gene Collection	2002–(ongoing)	**http://zgc.nci.nih.gov/**	More than 3400 full-length ORF zebrafish clones have been produced through this initiative sponsored by the National Institutes of Health and are available for public research.
WashU Xenopus EST Project	1999–2002	**http://genome.wustl.edu/est/index.php?xenopus=1**	cDNA libraries produced by the Xenopus research community and CGAP prior to 2002 have been arrayed by the I.M.A.G.E. consortium and sequenced at Washington University.
NIH Xenopus Gene Collection	2002–(ongoing)	**http://www.ncbi.nlm.nih.gov/genome/flcdna/prj.cgi?prjid=15**	More than 600 full-length ORF Xenopus clones have been produced through this initiative sponsored by the National Institutes of Health and are available for public research.

University of Iowa Rat project	1998–(ongoing)	**http://ratest.eng.uiowa.edu/**	Clones from this project are arrayed and sequenced at the University of Iowa, sponsored by the National Institutes of Health. Unique clones are rearrayed and given I.M.A.G.E cloneIDs (located in the comment field of the Genbank entry). 25 000 of these sequence-verified clones are currently available through the I.M.A.G.E. distributors.
The Mammalian Gene Collection (MGC)	1999–(ongoing)	**http://mgc.nci.nih.gov/**	Initiated in 1999 as a collaborative effort between various institutes of the NIH, the Mammalian Gene Collection project aims to provide a catalog of full-length mammalian genes (Strausberg *et al*., 1999). The project has focused initially on the production of full-length cDNAs for human and mouse, and will later extend to include other mammals. Clones produced by the project are prepared from high quality mRNA extracted from cell lines or tissues. Clones are made available through the I.M.A.G.E consortium, while 3′ and 5′ ESTs are generated and released to dbEST. An ongoing informatics challenge is the selection of clones likely to represent full-length transcripts. In the initial phases of the project, clones with inserts of up to 3 to 4 kb were sequenced using techniques such as shotgun sequencing, primer walking, and concatenation. Sequence data is generated to the same standards as those specified by the Human Genome Project – finished sequence is therefore 99.99% accurate. Annotation of the sequence data is also performed. As of January 2002, a nonredundant set of more than 20 000 putative full-length human and mouse clones have been identified and full sequences for 9000 human and 4000 mouse clones have been produced. 75% of the selected clones contain full-length ORFs. Clone library lists, clone lists, and insert sequences in FASTA format are available for download from **http://mgc.nci.nih.gov/**. Sequenced clones can be searched using BLAST at the same site. Additionally, the genes represented by MGC clones can be searched by gene name or keyword at the website.

Table 3 I.M.A.G.E. consortium clone distributors in Europe and the United States of America

Continent	Distributor	URL	Description
Europe	RZPD	**http://www.rzpd.de/products/clones/**	As a nonprofit service facility, the RZPD provides research materials and data including cDNA clone sets. Nonredundant, sequence-verified cDNA clone sets are available for human, mouse, and rat, and full-length and open-reading-frame (ORF) clones are available for more than 30 organisms. More than 35 000 000 clones representing over 1000 cDNA libraries, including the I.M.A.G.E collection, are represented. The linking of various public databases to the available clone sets provides researchers with the ability to search for clones using Gene Data, Clone ID, Unigene Cluster, Chromosome Location, Genbank Accession ID, or Affymetrix Probeset ID.
Europe	MRC geneservice	**http://www.hgmp.mrc.ac.uk/geneservice/ index.shtml**	cDNA clone sets including the I.M.A.G.E, MGC, and NIA mouse cDNA collections, as well as other human, mouse, rat, *Drosophila*, *Fugu*, *Xenopus,* and chicken clones. Various software tools are provided to allow users to interrogate the clone sets.
USA	ATTC	**http://www.atcc.org/**	ATCC is a commercial distributor of the I.M.A.G.E., MGC, and NIA mouse clone sets, as well as variety of clones for human, mouse, rat, and pine. More than 500 000 partially sequenced cDNA clones representing the majority of human genes and more than 300 000 murine cDNAs and 20 000 rat cDNAs are represented in the collection.
USA	Invitrogen	**http://clones.invitrogen.com/index.php**	The clones distributed by Invitrogen are assembled from public resources including I.M.A.G.E. Researchers can search for clones of interest using CloneRanger™ (**http://clones.invitrogen.com/cloneranger.php**). Approximately 10 million clones across a wide range of species. The collection can be searched by clone ID, NCBI accession, Unigene cluster ID, LocusLink ID, keyword, sequence, or plate ID.
USA	Open Biosystems	**http://www.openbiosystems.com/clone_collections.php**	Open Biosystems distributes a large number of clone sets including the I.M.A.G.E. and Incyte sets. Organisms included are human, mouse, rat, dog, pig, *Drosophila, Xenopus, C. elegans*, monkey, and zebrafish. Clones can be searched by Genbank accession, gene name, and clone ID.

Specialist Review

Using ESTs for genome annotation – predicting the transcriptome

Eduardo Eyras
Pompeu Fabra University - IMIM, Barcelona, Spain

1. Introduction

One of the goals of genome projects is to obtain the most complete set of genes from the genomic sequence. Automatic "genebuild" pipelines are designed to produce a set of gene annotations on which validation experiments can be performed. Even though the computational analysis of several eukaryotic genomes has been already carried out, the problem of automatic gene annotation is far from being solved. Different methods exploit a variety of biological data and hypotheses. A standard data source used for genome annotations is expressed sequence tags (ESTs), which from their origin (Adams *et al*., 1991) have played a very important role in the discovery of new genes. In spite of the experimental errors associated with ESTs (*see* Article 78, **What is an EST?**, Volume 4), they were soon recognized as a useful resource for genome annotation (Bailey *et al*., 1998). ESTs represent snapshots of the set of spliced mRNAs in a genome, the transcriptome, and in a given set of cell conditions. It is not clear how much of the transcriptome is represented by the ESTs, but they approximate a random sampling of the expressed genes as they are not necessarily constrained to any particular group of functional families. ESTs, besides enabling the detection of novel gene signals, also give information about possible alternative splicing patterns, polymorphisms, and untranslated regions in genes, complementing usual methods of annotation and ab initio gene prediction. We present here some of the advantages of using ESTs for genomic annotation, the potential problems, and possible solutions to them.

There are major issues regarding the quality of the EST datasets that must be handled before using them for genome annotation (Sorek *et al*., 2003). First of all, EST sequences are unverified single pass reads with an error rate that can be as high as 3% (Hillier *et al*., 1996). Moreover, ESTs represent incomplete transcript information and are subject to vector contamination in the cloning process. There can also be genomic contamination from the same organism, which would give false gene signals or incorrect splicing variations. An EST can also be part of a cDNA cloned from a pre-mRNA, which would give rise to an artifactual intron retention

event. Another problem in the ESTs is possible chimerism: cloned cDNAs may sometimes contain sequences from two different mRNAs, which can also lead to incorrect gene predictions. All these problems need to be addressed in any analysis involving ESTs. Some of the errors can be compensated for by the high redundancy of the data set, by imposing quality constraints in EST genomic alignments, or by using comparative genomics, whereas others require more specific curation.

2. Aligning ESTs to the genome

Before any metazoan genome sequence was available, ESTs were being used for finding genes. Since EST sequences are in general very redundant, a necessary step to look for genes is to cluster the ESTs according to sequence similarity (Adams *et al*., 1991; Schuler, 1997; Burke *et al*., 1998; *see also* Article 88, **EST clustering: a short tutorial**, Volume 4 for details). In these methods, a consensus sequence is derived for each cluster. The aim is to provide a gene index, where each cluster represents a gene in the genome, with information about expression and potential splicing variations (see Bouck *et al*., 1999 for a review). However, there are some problems inherent to these methods. In the process of building the clusters, it is difficult to avoid the placement of two paralog gene sequences in the same cluster, resulting in overclustering. On the other hand, very strict clustering can lead to genes being split into several clusters. Another problem is chimerism, since it can lead to the merging of two genes into one single cluster. Furthermore, owing to the high rate of EST sequencing error, it is sometimes difficult to distinguish an alignment gap from an event of alternative splicing. These problems can be avoided when considering the alignment of the ESTs to the genome. In fact, with the availability of genome sequences, EST self-clustering methods have been expanded to use genomic information, therefore improving the quality of the gene indices.

Here we will consider the approach of first aligning the individual EST sequences to the assembled sequence of a genome, and then, as explained below, clustering these EST alignments according to their exon–intron structure. There are several advantages to this approach, especially, when the sequence and the assembly are of good quality. First of all, it delineates the location of exons and introns in the genomic sequence. This allows the verification of the splice site signals, which enables the assignment of an EST to the correct strand. Low EST sequence quality is reflected as low alignment score and a higher frequency of frameshifts with respect to the genomic sequence. However, using identity thresholds above the expected error rate can avoid many mispredictions. The standard lower bound used for alignment similarity is 97% identity, which is consistent with the error rate mentioned before. Traditionally, the identity threshold is considered over a fixed distance on the EST, usually 50–100 bp. This is done to avoid cases where, for instance, an EST might have several segments aligned at 100% identity and some others at only 60% while still maintaining an average percent identity above threshold.

A standard quality test for an EST alignment is the verification that the splice sites defined by the alignment are canonical. There are three types of canonical introns commonly found in eukaryotes. These are characterized by the dinucleotides

GT-AG, GC-AG, and AT-AC. However, a number of ESTs define splice sites with noncanonical dinucleotides. Some variations might be spurious (Sorek *et al*., 2003) and some might correspond to novel splice sites (Burset *et al*., 2000). In spite of having canonical introns, some alignments can still define exon–intron boundaries with small variations between different ESTs. To avoid this, one can use a consensus approach, taking the most commonly used splice site. In principle, when ESTs from multiple libraries confirm the same splicing event, there is some added reliability to the definition of the intron, whereas an event present in only one EST library might be symptomatic of a sequence error or perhaps some sort of contamination.

For single-exon ESTs, which align as one single block in the genome, there can be ambiguities in the strand to which the exon should be mapped. This can be resolved for some cases using the coding bias of the exon sequence. About 60% of the human ESTs align as single exons on the genomic sequence. Many of these ESTs overlap with the 5′ or 3′ end of a known gene or a spliced EST, providing evidence for possible untranslated regions (UTR). The 3′ ESTs can sometimes align in separate clusters downstream of a gene, indicating possible alternative polyadenilation sites. Other single-exon ESTs can be found in isolation from any other gene features. It is difficult to determine whether these indicate single-exon genes or simply genomic DNA contamination. We would need to test these cases using codon-bias or protein similarity. However, this approach could potentially reject genes with unusual codon-bias that are underrepresented in databases. All these issues make single-exon genes difficult to annotate with ESTs.

Another problem that can be avoided by using genomic alignments is chimerism. Chimeric ESTs would be split into multiple chromosomes or perhaps define a suspiciously long intron on one chromosome. For this reason, it is standard to set an upper bound for allowed intron lengths, usually at around 200 kb, which will avoid chimeric ESTs that split on the same chromosome. Similarly, chimeric ESTs that split into different chromosomes can be avoided by setting a lower bound for the alignment coverage. This is usually chosen to be about 90%. This condition can also avoid possible undetected vector and cross-species contamination, as in these cases the EST would not be expected to align well. On the other hand, by consistently clipping a number of bases from both ends of the ESTs, one can increase the overall coverage of the alignments and keep ESTs that would be otherwise rejected. This clipping would eliminate some of the vector contamination and the poorer quality sequence, which is usually found at the ends. EST sequences in databases can also contain polyA or polyT tails, which should also be clipped prior to the alignment.

The thresholds used in genome alignments are usually higher than those used in EST self-clustering, hence when the genome sequence is of high quality we can gain in specificity over those methods, avoiding the problems derived from the clustering of paralogs. On the other hand, a problem in the genomic approach lies in potential genomic contamination and aberrant splicing. Errors in the splicing machinery could be overrepresented in ESTs owing to the repeated sequencing of the same genes. As pointed out before, although redundancy in the EST data can introduce noise, it can also provide a way to determine by consensus the correct splice sites annotations.

The aim of genebuild pipelines (for more details see Curwen *et al*., 2004) is to delineate all possible functional elements in a genome, in particular, all transcripts encoded in the DNA sequence. This task is usually split into parallel analyses for protein-coding genes, noncoding RNAs, and pseudogenes. ESTs are particularly valuable for detecting UTRs and alternative splicing in coding genes. However, ESTs can detect pseudogene signals as well and misguide the annotation of coding genes. In dbEST (Boguski *et al*., 1993), there are only a few human ESTs reported to be similar to known pseudogenes. However, as ESTs are gene fragments, there is an increased chance of aligning them to pseudogene loci. In the case of processed pseudogenes, one can define some heuristics to identify them. For instance, when a transcript sequence is compared to the entire genome, if the best alignment is spliced, any subsequent unspliced alignment of the same sequence elsewhere in the genome can be considered a candidate for a processed pseudogene. Potential pseudogenes can be further verified by testing for the absence of sequence homology in a closely related genome (Hillier *et al*., 2003). Additionally, one can search for other signals in the genomic sequence such as the presence of a downstream polyA tail, absence of the 5′ end of the transcript, in-frame stop codons and the presence of repeats within introns. All these tests are of course more effective with full-length cDNAs than with fragmented EST data.

Alternatively, one can rely on independent pseudogene annotations to avoid annotating these loci with ESTs. These annotations, however, are not easy to produce for novel genomes, for which there is not so much known gene data, and where ESTs play a role in the first-pass genome annotation effort. ESTs can also identify noncoding RNAs. For these cases, how to recognize and avoid pseudogenes remains a challenge.

ESTs reflect the sequence similarities between gene families. Thus, ESTs can potentially detect multiple gene loci sharing domains or perhaps even UTRs. Using the alignment thresholds given above, taking the best alignment plus any other alignment within 2% of the coverage, and using the above heuristics to avoid pseudogenes, we have found that nearly 10% of the alignable ESTs can align in more than one locus in the human genome, and about 2% align in more than one chromosome. On the other hand, it would make sense to pick only the best-in-genome alignment, as each EST is expected to come from a unique gene sequence. This would also reduce the misassignment of ESTs to gene loci. Accordingly, EST alignments to DNA sequence are most meaningful when performed as a comparison against the entire genomic sequence. This is complicated by the fact that nearby gene loci can sometimes combine in a unique transcript unit (Thomson *et al*., 2000).

The problem of aligning ESTs to a genome becomes a technical challenge when considering the human genome, with a size of about 3 Gb, and the approximately 5 million of ESTs currently available in dbEST (Boguski *et al*., 1993). This requires massive computational power and specialized alignment software that can not only process this amount of data in a reasonable time but which is also able to produce the correct alignment. The traditional approach is hierarchical. First, a fast and approximate alignment is produced that helps reduce the search space. Subsequently, the ESTs are more precisely aligned to this reduced space with a more accurate and computationally intensive method. In the last few

years, a new generation of programs have been produced that can manage this process in one step for an entire genome very quickly: BLAT (Kent, 2002) and Exonerate (Slater, **http://www.ebi.ac.uk/~guy/exonerate/**). The point of such methods is to be very competitive in speed and at the same time use an intron model sophisticated enough to extract an accurate exon–intron structure for the cDNAs and ESTs. A major objective of annotating genomes with ESTs is the delineation of introns and exons correctly on the genome sequence, rather than just the production of a consecutive block of alignments without contextual information.

ESTs are usually used in combination with cDNAs and mRNAs to obtain more complete information. Recent full-length cDNA sequencing projects are therefore very useful for improving our knowledge of protein-coding genes and the transcriptome. However, these projects seem to generate antisense transcripts as well (Kiyosawa *et al*., 2003): These are full-length cDNAs that align perfectly onto the genome sequence but that most often lack any recognizable open reading frame (ORF) and usually align on the opposite strand of a protein-coding gene. Moreover, they may play a regulatory role in eukaryotes (Lehner *et al*., 2002). Accordingly, one may suspect that EST datasets might contain sequences from these antisense transcripts, which might misguide the protein-coding gene search. Using the properties of the antisense RNAs, ESTs could be used to detect antisense transcripts in a genome with a good available annotation. However, in the case that ESTs are used to annotate a genome for which there are few, if any, annotations, it would remain difficult to properly identify antisense RNAs.

3. Expression data

The library of origin of the ESTs (*see* Article 80, **EST resources, clone sets, and databases**, Volume 4) supplies useful information about expression in an organism. Using sequence similarity between gene transcript sequences and ESTs, one can derive information about expression patterns. If, moreover, one uses the exon–intron structure of genes and ESTs, this association with expression information can be done more accurately: an EST is associated to a particular splice form of a gene when the exon–intron structures of both are compatible and in the same genomic locus. In this way, gene predictions can be linked to expression data. Using this method, the eVOC expression vocabularies (Kelso *et al*., 2003), based on normalized EST libraries for human, are linked to the Ensembl predictions (Curwen *et al*., 2004), providing a qualitative expression profile in silico. Likewise, this mapping can be carried out with nonnormalized libraries, providing quantitative information of expression.

Although EST data does not necessarily represent an exhaustive sampling of all cell states, a careful analysis of the expression data allows the identification of splice forms that are potentially specific to particular tissues, and in particular, specific to a disease state (Xie *et al*., 2002; Xu *et al*., 2002; Xu *et al*., 2003; Wang *et al*., 2003). Experimentally, one could scan multiple libraries to cover as many cell conditions as possible. However, every time ESTs are sequenced, we are not any closer to obtaining the complete set of transcripts for that library. In fact, the

same sequence may be read over and over, and lowly expressed genes may remain undetected. As a consequence, while the amount of EST data for human and mouse in dbEST is very large, this high redundancy has not necessarily added any new information. On the contrary, high redundancy can add extra noise and make the annotation of exons and transcripts more difficult. In the case of human and mouse, it is often necessary to perform a very strong filtering of the EST alignments to avoid this noise in the results. Filters can be based simply on duplicated alignments or on higher coverage and identity thresholds. It would be convenient to identify a selective procedure to sequence ESTs from genes that are expressed at very low level, or with a very restrictive pattern of expression.

4. Predicting the transcriptome

Most of the evidence for splicing variation in the human genome observed so far has been based on ESTs (Mironov *et al*., 1999; Brett *et al*., 2000; Modrek *et al*., 2001; Modrek *et al*., 2002; Kan *et al*., 2002). The standard method has been until now to infer local variations of splicing events from the exon–intron structures of the ESTs. Some of the methods are based on variations with respect to mRNA sequences aligned to the genome (Kan *et al*., 2002). Other methods have used the clusters from EST self-clustering and aligned those to the genome.

However, in order to properly define the proteins encoded in the transcriptome, one needs to derive the complete sequences for the alternative forms. This has motivated the development of new methods of transcript prediction from ESTs (Kan *et al*., 2001; Wheeler, 2002; Haas *et al*., 2003; Xing *et al*., 2004; Eyras *et al*., 2004). Genome-based methods base the joining and merging of ESTs on the exon–intron structure. The initial step of sequence similarity is dealt with at the alignment step and the analog of the consensus sequence is here the genomic sequence itself. In this way, the redundancy of the ESTs is translated to splicing structure redundancy. In general, one EST can be part of one or more putative transcripts, as sometimes one cannot uniquely specify the possible full transcript from which it originated. This is the case, for instance, for ESTs that align on constitutive exons. The transcripts produced should not be a combinatorial enumeration of all possible splice site concatenations. Rather, the complete exon–intron structure given by the experimental evidence should be taken into account by the algorithm. This is important in order to reflect the possible global dependencies of the splice events in the final predictions. We are, however, limited by the fragmented nature of the ESTs. By taking a random sampling of tags from known mRNA sequences and maintaining the global dependencies of the simulated tags, genome-based methods can recover the original transcript structures. However, it is still possible that transcripts not present in the original set might be produced. Indeed, no matter the depth of the EST sequencing, short ESTs do not add any knowledge about alternative splicing, and there is an increased uncertainty for every two consecutive sites of alternative splicing that are not covered by at least one single EST (Eyras *et al*., 2004).

In general, we expect many of the predicted transcripts to be partial or even complete coding sequences. Some of them might give rise to new protein sequences,

while others will match known ones. This can also be used as a validation of the predictions. EST-derived transcripts can be searched against databases of known proteins to determine homologies. This, however, can yield a large number of false-positives (Jongeneel, 2000). There are also a number of statistical models that predict the coding regions in ESTs taking into account, among other factors, the transition between UTR and coding sequence. This can also help predict the UTRs in genes, and equivalently detect possible noncoding RNAs. These methods, however, use the bias in coding nucleotide sequences, hence possibly overlooking protein-coding transcripts with unusual codon-bias.

Conservation at the level of sequence implies a functional relevance; hence, we expect many of the expressed sequences to be conserved between closely related species. This can also serve as a validation of the splicing structures and predicted proteins. Alternative splicing has been estimated to be 60% conserved at the splice-junction level between human and mouse (Thanaraj *et al*., 2003). Furthermore, some forms of alternative splicing (*see* Article 78, **What is an EST?**, Volume 4) appear to be more conserved than others (Sugnet *et al*., 2004; Kan *et al*., 2004). We would then expect to find some conservation at the transcript level, keeping in mind that there seems to be no conservation for some classes of genes (Nurtdinov *et al*., 2003). Determination of conservation of the predicted complete transcripts can be carried out at two levels: the sequence level (transcript comparison) and at the splicing structure level (exon–intron comparison between the orthologous genomic regions). The two comparisons together can increase our specificity when assigning conserved structures. This defines a notion of transcript orthology, which has been used to validate transcripts predicted from ESTs in (Eyras *et al*., 2004). Using these methods, one observes that 20% of the transcript variants in human are also found in mouse as predicted from ESTs (data not published). In fact, we expect many more variants to be conserved, as the available EST data is not exhaustive due to the possible differences in sampling between human and mouse.

In general, genome annotation is traditionally based on sequence homology searches and ab initio prediction methods. However, when there is little species specific data or the known gene sequences for closely related genomes are not very well conserved, homology-based methods have a limited predictive power, hence it is necessary to rely on ab initio methods. These methods need, in general, a training set, usually consisting of experimentally verified genes, which for some genomes can be limited. EST sequencing can provide a head start for automatic annotation in these cases. Methods such as ClusterMerge (Eyras *et al*., 2004) can produce transcript predictions from the available ESTs and cDNAs. These transcripts can serve in principle as a first-pass genebuild. As some of the predicted transcripts are bound to be incomplete, the defined transcripts can be used as evidence for gene predictors in order to complete the transcripts according to the contextual genomic sequence (Howe *et al*., 2002), increasing the power of usual gene-prediction methods. Furthermore, EST-based transcripts can also provide spliced structures on which to train the gene-prediction models. This opens up many new possibilities, as gene models could eventually be created according to specific splicing structures and different coding biases. These training methods could be valuable to predict genes according to specific patterns of expression and perhaps also for developing ab initio predictors of genes with alternative splicing. Gene-prediction models that

can incorporate this type of information would be very valuable for the automatic annotation of genomes.

ESTs remain a crucial data source for transcript-discovery tools, and their potential is not yet exhausted. Handling this type of data is not easy, but the amount of potentially useful information is worth its use. Knowing well the pitfalls of EST data and developing methods that take these into account can provide very useful information for genome annotation.

Specialist Review

Using ORESTES ESTs to mine gene cancer expression data

Sandro J. de Souza, Pedro A.F. Galante and Rodrigo Soares
Ludwig Institute for Cancer Research, São Paulo, Brazil

1. Introduction

The major challenge facing biologists following the completion of the Human Genome Project is the complete characterization of the human transcriptome. It is absolutely crucial that we understand how the expression of a given gene affects the onset of a given trait, either normal or pathological. For obvious reasons, one disease model that has attracted a lot of resources and efforts is cancer. The amount of data on expressed genes in cancers has grown exponentially in the last 15 years. Since the development of the EST (Expressed Sequence Tags) technology in the early 1990s (Adams *et al*., 1991), the contribution of ESTs derived from cancer samples in the public databases has been substantial. Today, more than 50% of all human ESTs in dbEST correspond to sequences derived from more than 50 types of tumors. Although efforts from individual laboratories were, and still are, important for the development of public repositories of cancer-oriented data, the emergence of large-scale sequencing projects was crucial especially due to the amount of data generated. As recently compiled by Strausberg *et al*. (2003), there are two major cancer-oriented genome projects that focus their efforts in the transcriptome: the Cancer Genome Anatomy Project (CGAP) and the Fapesp/Ludwig Human Cancer Genome Project (HCGP). The CGAP's main objective is the integration of genomics and cancer research (Strausberg *et al*., 1997; Strausberg *et al*., 2000). An index of genes expressed in cancer cells and their normal counterparts has been achieved in CGAP through the use of both the EST and the Serial Analysis of Gene Expression (SAGE) (Velculescu *et al*., 1995) technologies. HCGP centered its efforts in the generation of ESTs from a variety of tumors frequently found in the Brazilian population. The project employed a new methodology called *Open-reading frame EST sequencing* (ORESTES) (Dias-Neto *et al*., 2000), which generates ESTs from the central part of the transcripts (see details below).

The availability of the human genome sequence represented a significant boost in cancer research and increased the value of the transcriptome databases. Owing to the poor efficiency of *ab initio* gene prediction, transcriptome data proved to be essential in finding genes in the genome sequence (Lander *et al*., 2001; Venter *et al*.,

2001). Moreover, the human genome sequence provides a framework from which data from diverse sources can be viewed in an integrated manner. This integration allows the use of databases like OMIM (**http://www.ncbi.nlm.nih.gov/omin**) that record information of genetically inherited diseases, in conjunction with the cancer-oriented transcript databases. This integration has speeded up the finding of cancer-related genes.

Here, we will discuss some strategies to mine cancer-oriented transcript databases, with a special emphasis on the data produced by HCGP.

2. HCGP

The HCGP was launched in 1999 with funds provided by the Ludwig Institute for Cancer Research and Fapesp (the State of São Paulo Research Foundation). The basis of the project was the sequencing of transcripts expressed in different types of tumor cells and their normal counterparts. Here lies the most important aspect of the HCGP. The strategy used to generate the ESTs was ORESTES, which provides sequences mainly from the central part of the transcripts. In this aspect, the HCGP data complements data from other EST projects, especially CGAP, which target the extremities of the transcripts. Figure 1 illustrates this aspect of the ORESTES data. ORESTES is characterized by the generation of sequences through a low-stringency PCR reaction using arbitrary primers (Dias-Neto *et al*., 2000). Besides providing sequences from the central part of the transcript, the low-stringent PCR reaction is expected to provide a normalization effect to the set of generated sequences (Dias-Neto *et al*., 2000). The success of HCGP has stimulated the use of ORESTES in another large-scale EST sequencing project (Verjovski-Almeida *et al*., 2003).

More than 820 000 sequences were deposited in public databases (Table 1). A comparison involving ORESTES and UniGene (Build # 163) is presented in Table 2. Almost 500 000 ORESTES are present in UniGene, distributed in 52 072 clusters. UniGene clusters containing at least one ORESTES and onek nown mRNA (mostly derived from large-scale full-insert sequencing projects) comprise 18 532, while 33 540 clusters contain only ESTs. Interestingly, there are 15 508 UniGene clusters that contain only ORESTES sequences. This is unexpected because UniGene is a 3′-oriented transcript database, and ORESTES is biased toward the central part of the transcripts. However, UniGene has recently modified its strategy of building clusters with the incorporation of the genome sequence (**http://www.ncbi.nlm.nih.gov/UniGene/**). Since there is still no detailed description of this new clustering methodology, it is impossible to evaluate the

Figure 1 Schematic view of all transcripts from UniGene cluster Hs. 287.666 (Build 163). Observe that ORESTES are preferentially located at the central part of the transcript

Table 1 ORESTES in dbEST. Only main tissues are listed

	Normal	Tumor	Total
Total number deposited			823.121
Breast	59 991	73 354	133 345
Colon	8814	69 419	78 233
Head/neck	1917	149 703	151 620
Brain	46 023	20 883	66 906
Prostate	19 002	19 182	38 184
Stomach	13 756	38 916	52 672

ORESTES in UniGene	497 610
Clusters with ORESTES	52 072
Clusters with ORESTES + mRNAs	18 532
Clusters with ORESTES only	15 508

Table 3 ORESTES mapped onto the genome sequence. Protocols for mapping and clustering can be found at Sakabe *et al*. (2003) and Galante *et al*. (2004)

ORESTES mapped	565 535
ORESTES defining >1 exon	185 525
Clusters with ORESTES	118 573
Clusters with ORESTES only	76 456

significance of these clusters. When integrated to the genome sequence, 565 535 mapped ORESTES sequences defined 118 573 clusters (Table 3). Details on the mapping and clustering strategy can be found in Sakabe *et al*. (2003) and Galante *et al*. (2004). A fraction of the mapped sequences (185 525) defines more than one exon at the genome level. More than 6100 new exons have been defined by these ORESTES sequences.

The unique features of the ORESTES sequences have implications for the mining process. It has been shown, for instance, that ORESTES are preferentially located at the central part of the transcript and therefore represent best the coding region (Dias-Neto *et al*., 2000; Camargo *et al*., 2001). Furthermore, the ORESTES dataset is enriched with sequences derived from rare messages (Dias-Neto *et al*., 2000; Sakabe *et al*., 2003). Those features make the ORESTES collection enriched with cDNAs corresponding to coding regions of rare transcripts. Below, we will discuss some strategies to mine the ORESTES dataset.

3. Identification of genes differentially expressed in tumors

Identification of genes that are differentially expressed in tumors is one of the most important forms of mining the cancer-oriented transcript databases. Several

reports have been published in which such genes were successfully identified by ESTs (Schmitt *et al*., 1999; Welsh *et al*., 2001; Scanlan *et al*., 2002). The use of ESTs in quantitative analysis of gene expression is a controversial issue. Owing to the heterogeneous nature of the EST data, with many sequences coming from normalized libraries, the absolute frequency of a given transcript in the EST database does not directly reflect its abundance in the cell's transcriptome. The same is true for the ORESTES collection of sequences due to the normalization effect of the methodology. It is advisable then to use the ORESTES sequences coupled to a more quantitative measurement of gene expression, such as SAGE.

We have developed an electronic protocol for the identification of genes differentially expressed in any tissue by using both ORESTES and SAGE (Leerkes *et al*., 2002). Assuming that one has a large amount of ORESTES for a given tumor and its normal counterpart, these sequences can be used to identify candidate genes to be differentially expressed in tumors. This analysis is used as a starting point to guide subsequent analyses. A critical issue when using ORESTES for the identification of differentially expressed genes is the collection of primers used to construct the respective libraries. In comparing ORESTES from two samples, it is important that all sequences came from libraries constructed using the same set of arbitrary primers. Otherwise, the pool of genes represented in each set will be different and false positive candidates will be identified. Clustering of sequences is also important to allow a comparison of the number of sequences in each cluster in the two samples being analyzed. In the final step of the protocol, SAGE is used to corroborate the analysis done using only ORESTES. We have used this protocol in a comparison of 21 437 and 37 890 ORESTES from normal and tumor breast, respectively (Leerkes *et al*., 2002). We were able to identify 154 genes as candidates for being differentially expressed in tumors. Among these, 28 have been shown to be overexpressed in tumors. We obtained 82% of success in experimental validations for 11 candidate genes.

4. Identification of new transcribed regions in the human genome

Expressed sequences have been critical to the identification of human genes (Lander *et al*., 2001; Venter *et al*., 2001). Not surprisingly, the ORESTES dataset has contributed significantly to this process, especially due to the central distribution of the sequences and the normalization effect. It is expected that the ORESTES collection is enriched with transcript sequences spanning exon–exon boundaries, especially if compared to 3′ ESTs, due to the fact that introns are less frequently found at the 3′ end of genes. ESTs that align continuously along the genome are of dubious quality since they can represent genomic contaminants. Thus, ORESTES sequences are important for the unambiguous identification of genes.

We have used 250 000 ORESTES from a variety of tumors to identify a new transcribed region in chromosome 22 (de Souza *et al*., 2000). All these sequences were mapped onto chromosome 22, and a comparison with previously annotated transcribed regions in this chromosome was made. We found 219 new transcribed

regions in chromosome 22. Since the ORESTES sequences are not indexed to a specific region of the transcript, it was impossible at the time of original mapping to define the number of new genes discovered by ORESTES in chromosome 22. For this report, we compared this 219 transcribed regions with the mapping of all known human mRNAs, and observed that for 90 of them there was already a matching known human mRNA reported after the publication of our original analysis.

The integrated approach of mapping all human ESTs onto the sequence of the human genome has been very fruitful in terms of characterizing new genes. For example, 19 additional genes were found in chromosome 21 through the use of mapped ESTs and a set of stringent criteria to identify reliable 3′ ends (Reymond *et al*., 2002). Interestingly, these new genes are small and poorly represented in the cDNA databases.

A different but powerful strategy for characterizing new human genes has been proposed by us (Camargo *et al*., 2001). In this strategy, clusters of ESTs mapped onto the genome sequence can be used for direct gap closure. RT-PCR experiments with primers designed based on the sequence of neighbor clusters form the basis of such strategy. As proof of principle, Camargo *et al*. (2001) characterize four new human genes. This transcript finishing strategy is been used in a context of a large-scale initiative that so far has characterized hundreds of new human genes (Sogayar *et al*., 2004).

5. Identification of splicing variants differentially expressed in tumors

A fascinating new perspective on the human transcriptome has emerged in the last few years. The degree of variability found at the transcriptome level greatly exceeds previous estimates. One of the major sources of variability is alternative splicing, which seems to occur in at least half of all human genes (Mironov *et al*., 1999; Modrek *et al*., 2001; Sakabe *et al*., 2003).

We recently reported an interesting case of a splicing variant of the gene *NABC1* (Correa *et al*., 2000), which uses a previously unidentified 135-bp exon (NABC1_5B), through the mapping of an ORESTES sequence to the human genome. Collins *et al*. (1998) reported that NABC1 is a strong candidate oncogene mapped to a genomic region frequently amplified in several types of tumors. These authors demonstrated that NABC1 is highly expressed in breast cancer cell lines. We confirmed the increased expression of NABC1 in breast tumor. We also showed that NABC1 and NABC1_5B are both underexpressed in colon tumors (Correa *et al*., 2000). ORESTES sequences have also allowed the characterization of splicing variants of the semaphorin 6B (Correa *et al*., 2001).

The unique features of the ORESTES sequences motivated us to perform a large-scale analysis of alternative splicing in these sequences (Sakabe *et al*., 2003). It is expected that the ORESTES dataset would be enriched with rare splicing variants, which affect the structure of the corresponding protein. We found that genes showing low expression, as evaluated by SAGE, contain more ORESTES than

other ESTs, reinforcing the normalization effect of the ORESTES methodology. Furthermore, less ORESTES are required to detect a splicing variant and the ORESTES dataset is enriched with variants that affect the coding region of human genes, a feature derived from its biased distribution along transcripts. We found that 85% of all events detected by ORESTES are within the coding region, while 77% of the events detected by conventional ESTs are within this category ($p < 0.001$) (Sakabe *et al*., 2003).

These features of ORESTES regarding alternative splicing make the methodology an efficient platform for an exhaustive coverage of the variability in the human transcriptome.

6. Final considerations

The importance of mining cancer-oriented transcript databases is clearly evident in the last 10 years. While the major efforts have been directed toward the characterization of new genes related to cancer and the identification of genes differentially expressed in tumors, new forms of exploring the data have emerged. The search for splicing variants differentially expressed in tumors is such an example. Another situation is the identification of SNPs from transcripts expressed in tumors (Brentani *et al*., 2003). Data from HCGP have been crucial in the development of the available cancer-oriented databases. More importantly, a very fruitful interaction between HCGP and CGAP teams was established (Strausberg *et al*., 2002b; Strausberg *et al*., 2003; Brentani *et al*., 2003), culminating with further contributions (Boon *et al*., 2002; Sakabe *et al*., 2003; Cerutti *et al*., 2003; Iseli *et al*., 2002; Jongeneel *et al*., 2003). This interaction was possible because of a common notion that the datasets were complementary as were the collection of tumors being approached by both projects. Fundamental was the commitment of both projects to the release of the data to the community. This common strategic view has allowed the emergence of integrated databases. SAGE Genie (Boon *et al*., 2002), for example, although structured around SAGE data, uses EST information to explore the effect of transcript variability on the gene-to-tag assignment. This and other successful interactions show that integration is the key for effective mining of cancer-oriented transcript databases.

Acknowledgments

The authors would like to thank all participants from both projects, the Ludwig/Fapesp Human Cancer Genome Project and the Cancer Genome Anatomy Project. PAFG is supported by a PhD fellowship form Fapesp.

Proteome knowledge bases in the context of cancer

Djamel Medjahed and Peter A. Lemkin
National Cancer Institute at Frederick, Frederick, MD, USA

1. Introduction and motivation

The origin of most cancers can be often traced to a single transformed cell (Fearon *et al*., 1987). The evolution of the disease follows a yet to be completely understood pathway of molecular transformations occurring at both genomics and proteomics levels. Most cancers show a significant preponderance to statistically originate from well-defined parts of their respective organs. It is then only normal that investigations to identify biomarkers indicative of the early onset of the disease be focused on these organ-specific regions.

This point was elegantly demonstrated by Page *et al*. (1999) in a careful experiment, in which they used magneto-immuno-chemical purification methods to extract pure cell populations and compare the protein expression observed in experimental two-dimensional Polyacrylimide Gel Electrophoresis (2D-PAGE) (O'Farrell, 1975; O'Farrell *et al*., 1977) maps obtained from normal, milk-producing luminal epithelial cells exhibiting a tendency to develop breast carcinomas versus outer, myoepithelial cells.

This thorough characterization was achieved by using a combination of enabling technological platforms (Aebersold *et al*., 2000; Bussow, 2001; Fivaz *et al*., 2000; Kriegel *et al*., 2000; Dihazi *et al*., 2001; Angelis *et al*., 2001; Weiller *et al*., 2001; Wulfkuhle *et al*., 2000) that allowed them to flag a number of proteins exhibiting a significant differential expression between the two types of cells, and therefore warranting a closer evaluation of their potential as biomarkers of breast cancer. The time and costs involved in using these techniques can be quite prohibitive, particularly on a large scale.

This led to the initial motivation to address the need that either on a routine basis, or to establish optimal experimental conditions before hand, one might be interested in predicting the gene products likely to be detected in narrow ranges of isoelectric focusing point (pI) and molecular weight (Mw).

We believe that the initial search for cancer biomarkers can greatly benefit by formulating the hypothesis developed from knowledge-based bioinformatic tools. We will now describe in some detail two such predictive databases whose development was at least in part motivated by these pressing issues.

2. VIRTUAL2D: a Web-accessible predictive database for proteomics analysis

2.1. Introduction

The growing use of immobilized pH gradients (Gorg *et al*., 2000; Bjellqvist *et al*., 1993) and automation in producing SDS gels has allowed the emergence of reproducible, high-resolution two-dimensional separation of proteins. Furthermore, the availability of databases of primary sequences of proteins, either directly determined or inferred from genome databases allows the validation of the contents of experimental 2D-PAGE maps (WORLD-2DPAGE, 2004). VIRTUAL2D (Medjahed *et al*., 2003b) is an interactive Web-accessible collection of reference, organism-specific, synthetic (pI, Mw) maps based on the consensus, published amino acid sequences.

The approach used to determine the isoelectric focusing point and molecular mass of a peptide can then simply be summed up as follows:

1. Scan the primary sequence of the peptide.
2. Assign the pK of each contributing amino acid according to Table 1.
3. Sum up all the mass contributions.

The resulting pI/Mw for the peptide is then given by the ratio of

$$Pk_{\text{tot}} = \frac{\left\{pK_{\text{Cterm}} + \sum_{\text{int}} pK_{\text{int}} + pK_{\text{Nterm}}\right\}}{(n-2)} \tag{1}$$

and

$$M_{\text{rtot}} = \sum_i M_t i.$$

where the pI summation runs over all n contributing, internal amino acids

2.2. Database mining

The resulting plot of pI versus the molecular mass yields a theoretical 2-D PAGE map with a striking bimodal distribution centered around pH 7.4–7.5. This feature seems to be shared by all organisms analyzed (Figure 1a,d). The biochemical justification most often advanced in explanation of this observation is that the majority of proteins would tend to naturally precipitate out of solution around the cytoplasmic pH of approximately 7.2. The pI is the pH for which the protein charge is overall neutral. It, therefore, represents the point of minimum solubility due to the absence of electrostatic repulsion, resulting in maximum aggregation. While this provides an explanation for experimental 2D-PAGE maps, we must remember that no such correction was incorporated in the modeling. What then is the basis for the separation of proteins into acidic and basic domains in computed pI/Mw charts? In our efforts to answer these questions, we carried out a simulation whereby

Table 1 Values of amino acid masses and pKs (determined (Gorg *et al*., 2000) at high molar concentrations of urea) used in pI/Mw computation. The segregation is underscored by the fact that the pKs of roughly half the internal amino acids fall below pH 6.0, while for the rest they are greater than or equal to 9.0

Ionizable group	pK	Molecular mass
C-terminal	3.55	
N-terminal		
Met	7.00	132.994
Thr	6.82	102.907

Asp	4.55	116.89
Glu	4.75	130.917

groups of 1545 peptides varying in length from 50 to 600 AA, in increments of 10 were randomly generated. This brings the total number of simulated sequences to 8 6520 versus 8 6518 real peptides extracted from current databases, thereby improving the prospects of any meaningful comparative statistics. As mentioned earlier, the calculation of the pI values is carried out iteratively. The pK of a peptide is calculated by tallying the contributions to the charge from the n-terminus, the c-terminus and the internal portion of the peptide. As can be observed in Figure 2, the resulting simulated pI/Mw distribution is strikingly similar to that adopted by the extracted sequences. While this may seem surprising at first, given the total absence of bias in both the lengths and content of the peptides used for the simulation, it is in fact a direct consequence of the constraints imposed by a limited proteomic alphabet of twenty amino acids with distinct pKs roughly half of which are either acidic or basic (Table 1).

In fact, as is reflected in Table 1, only seven internal amino acids make nonzero contributions to the pI of the peptide. These seven amino acids are: cysteine, aspartic acid, glutamic acid, histidine, lysine, arginine, and tyrosine. It is reasonable to suspect that a high percentage of the variation in the calculated pI values of the simulated data would be modulated by the representation of these seven amino acids,as the majority of the contribution to the charge comes from the internal portion of the peptide. To investigate the actual contribution of these seven amino acids in determining an overall pI value, a multiple regression model was developed using the adjusted numbers of these seven amino acids as predictor variables and

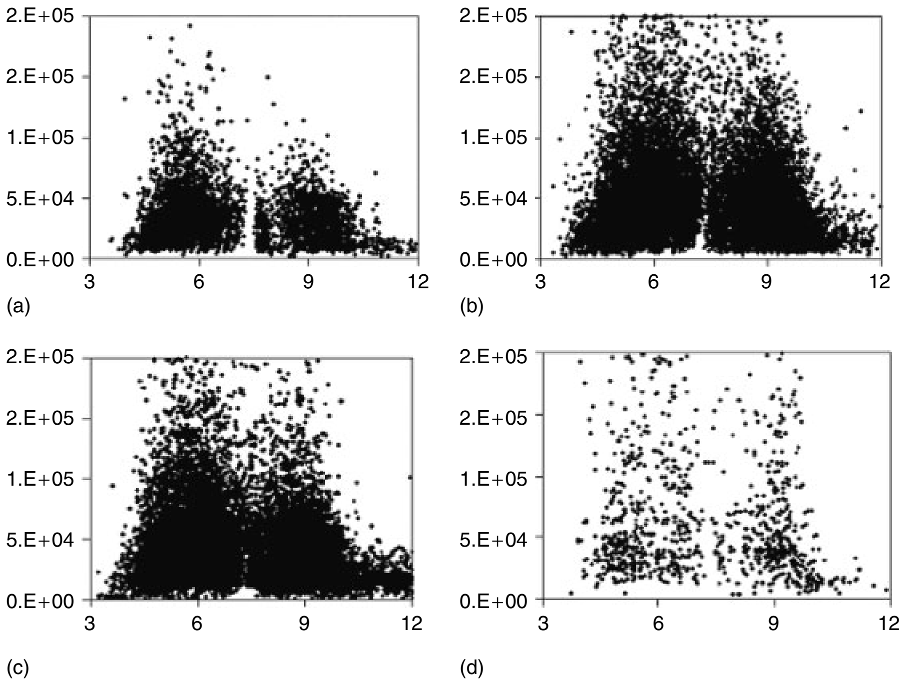

Figure 1 pI/Mw Map for several organisms. To keep in line with the experimental limits encountered in practice, the pI/Mw plot has been confined to less than 2×10^5 kD for the molecular mass and 3.0< pI < 12.0 for the isoelectric focusing point. (a) *E. coli*, (b) *Homo sapiens*, (c) mouse, (d) *Plasmodium falciparum*

the pI value as the dependent variable. The adjusted count for an amino acid is equal to the actual number of times the amino acid is found in the peptide divided by the length of the peptide. The adjusted counts will be denoted as follows:

aR = adjusted count for arginine
aC = adjusted count for cysteine
aD = adjusted count for aspartic acid
aE = adjusted count for glutamic acid
aK = adjusted count for lysine
aH = adjusted count for histidine
aY = adjusted count for tyrosine

The regression model in question uses the linear, quadratic, and cubic powers for each adjusted number of the seven amino acids that contribute to the pI calculation when they are part of the interior of the protein. A total of 21 independent variables were employed in the regression analysis. This analysis yields a multiple correlation factor R of 0.931. The coefficient of determination (the square of the multiple R) gives the proportion of the total variance in the dependent variable accounted for by the set of independent variables in a multiple regression model. For the model in question, 0.866 is the square of the multiple R. Consequently, 86.6% of the total variation in the pI values was accounted for by the aforementioned seven amino

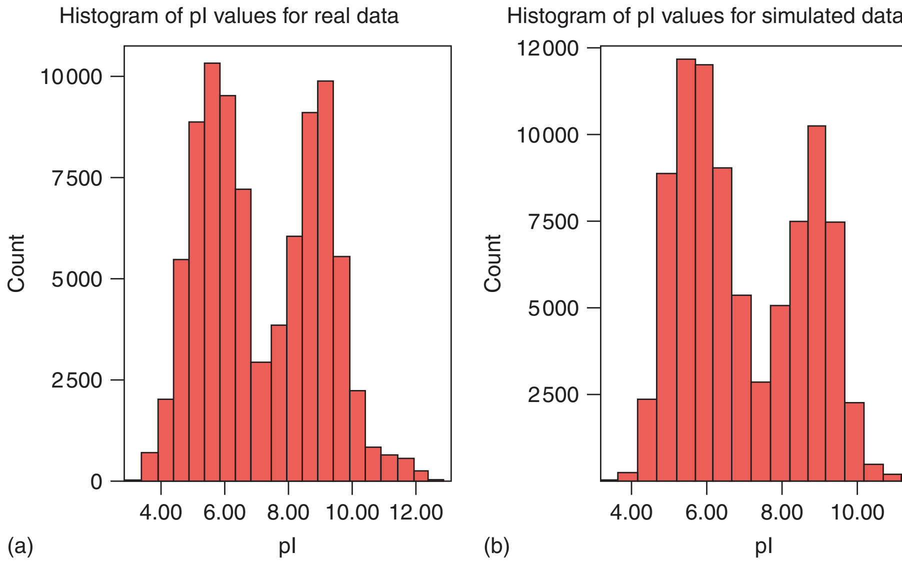

Figure 2 Side-by side comparison of ”pI/Mw” histograms for *Homo sapiens* (a) computed using amino acid sequences from TrEMBL/SWISS-PROTversus (b) randomly generated as described in the text

acids. The simulation result confirms the hypothesis that the total number of these seven amino acids is the key factor is explaining the pI value of a peptide.

The predicted pI score in the regression model is denoted as pI’, and it is the dependent (criterion) variable in the regression model. The equation for the regression model is:

$$pI' = a + \Sigma_i X_i \tag{2}$$

where a is the intercept of the model, b_i is the partial slope for the ith predictor in the model, and X_i is the ith predictor in the model. There will be 21 different predictors in the model: seven linear terms (aR, aC, aD, etc.), seven quadratic terms (aR^2, aC^2, aD^2, etc.) and seven cubic terms (aR^3, aC^3, aD^3, etc.). All parameters were estimated by ordinary least squares using the SPSS 8.0 computer package (SPSS, 2004).

The coefficient of determination or R^2 for the model is the proportion of variance of the pI values accounted for by the regression model. It is equal to the sum-of-squares regression divided by the total sum-of-squares:

$$R^2 = \frac{\Sigma pI' - <(pI)>)^2}{\Sigma(pI - pI')^2} \tag{3}$$

where

$$<(pI)> = \sum pi/N$$

A Perl script was written to process large organism-specific proteome datasets in FASTA format downloaded from the European Bioinformatics Institute (CEBI,

2004). It will output tab-delimited files of the molecular mass, pI, SWISS-PROT (SwissProt, 2004) accession number and identification for each protein entry. Inorder to increase the analytical value of Virtual2D to the scientific community, interactivity is built into these plots by implementing the following features (displayed in Figure 3).

- possibility to use the database on any JAVA-enabled computer;
- pan, zoom, and click features;
- with Internet connection, hyperlinks between each data point and popular databases (SWISS-PROT, NCBI, etc.).

2.3. Comparison with experimental data

Computed pI/Mw values were compared against those reported experimentally in two cases. In the first example, a high-resolution map for *Escherichia coli* obtained over a narrow pH range (4.5–5.5) was used. Landmarks provided by reference proteins whose characteristics were independently confirmed can be used to calibrate positions over the entire area of the image. pI, molecular masses, and relative intensities can then be determined by interpolation for all detected protein spots (Figure 4a). A minimally distorted "constellation" consisting of proteins whose predicted pI/Mw values are fairly close to their experimentally determined counterpart, displayed in Figure 4(b) can then be used in principle to "warp" (align) the experimental gel, onto the theoretical one.

2.3.1. Warping, defined

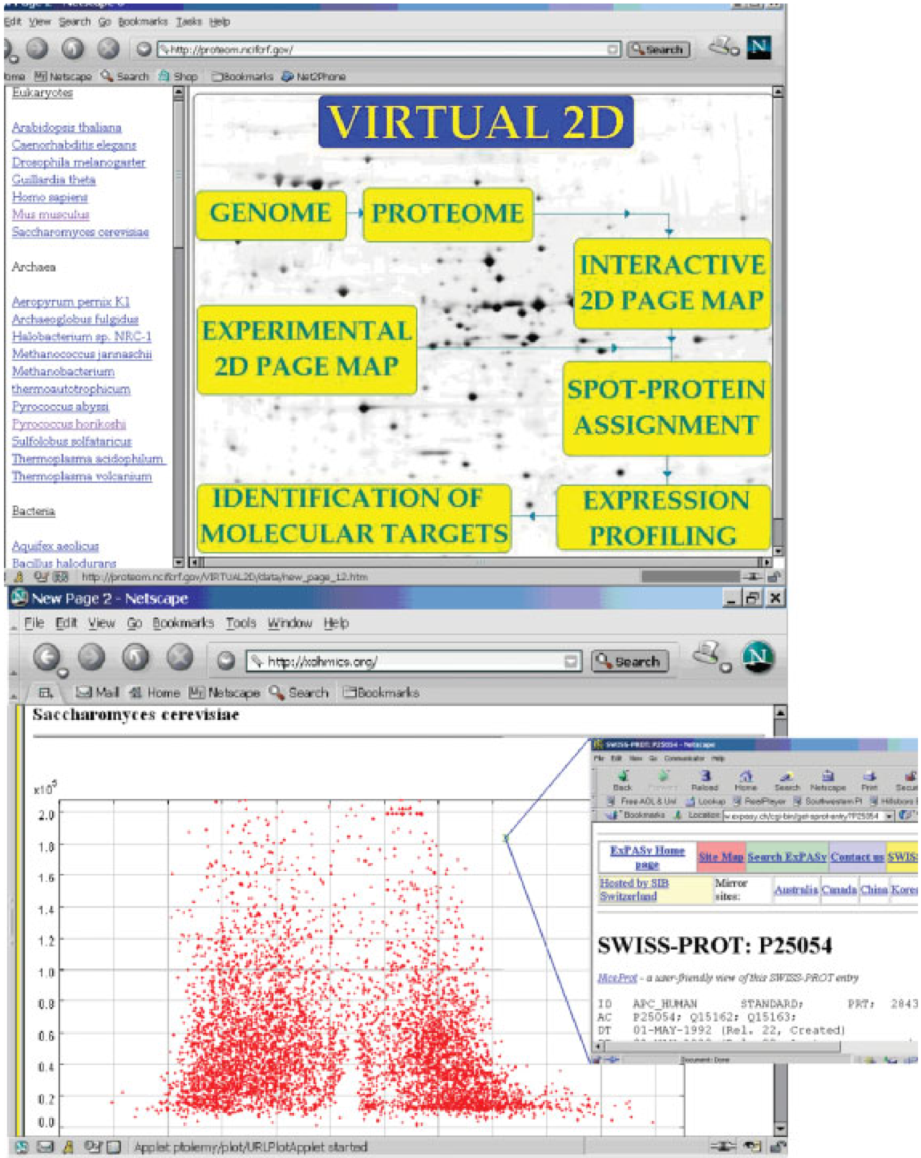
To understand warping in its simplest form, one can imagine dividing up the gel into several regions around each one of these pairs of spots so that for any given region, the local experimental landmark (brown circle) will be transformed to its predicted counterpart (blue square) by a translation specific to that neighborhood. Any experimental spot (including the landmark) within region 1, for instance, will undergo the same local translation defined by:

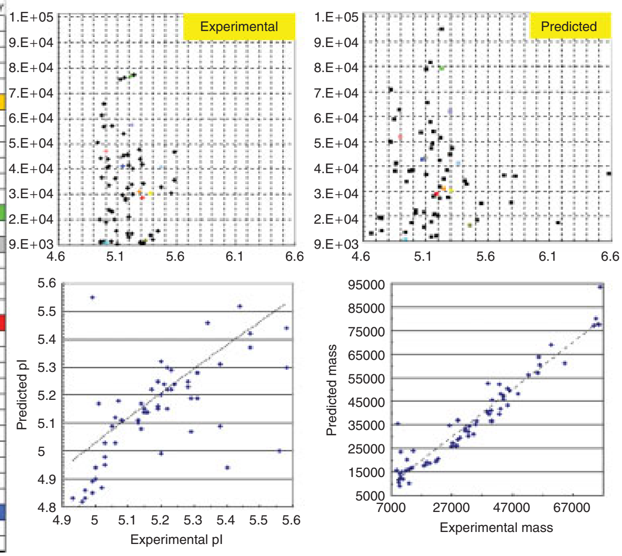
$$X_{\text{pred}} = X_{\text{exp}} + \Delta X_1 \qquad (4)$$
$$Y_{\text{pred}} = Y_{\text{exp}} + \Delta Y_1$$

where ΔX_1 and ΔY_1 are the components of the local translation needed to bring an experimental landmark onto its predicted counterpart. If the spot happens to be in region 3, then

$$X_{\text{pred}} = X_{\text{exp}} + \Delta X_3 \qquad (5)$$
$$Y_{\text{pred}} = Y_{\text{exp}} + \Delta Y_3$$

and so on.





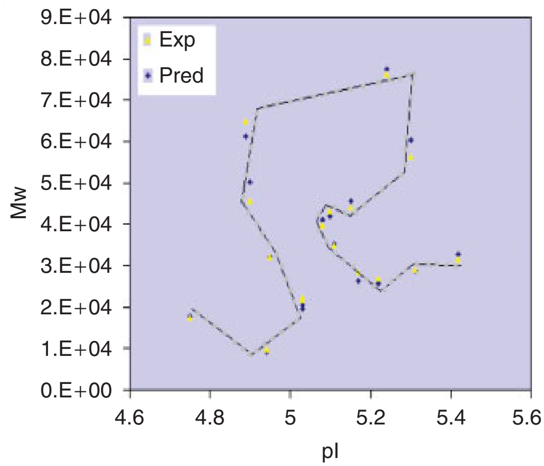


Figure 3 A snapshot of the screen display of VIRTUAL2D (**http://ncisgi.ncifcrf.gov/~medjahed**). Protein expression maps computed for 132 organisms/proteomes using data obtained from the European Bioinformatics Institute can be displayed by clicking on any of the entries on the left. On the fly interaction and identification. By using the controls, one can zoom in on a particular area. Simply moving the mouse over or clicking on any spot will either display a short description or bring up comprehensive information from the hyper-linked web server of choice (Protplot uses Java code modified from MicroArray Explorer; Lemkin *et al*., 2000)

(b)

Figure 4 (a) Comparison of the values of isoelectric focusing points and molecular mass extracted from a high-resolution *E. coli* 2D-PAGE map downloaded from SWISS-2DPAGE and those computed in this work. In the two upper charts, a small number of corresponding data points from each set have the same color for a quicker visual inspection. (b) For a small subset of proteins, computed pI/Mw values are fairly close to the experimentalcounterparts, providing a ”constellation” of reference points that can be used for warping

For those areas without designated landmark such as region 2, one can interpolate using the translations from the surrounding neighborhoods.

$$X_{\text{pred}} = X_{\text{exp}} + \Delta X_2 \quad \text{where} \quad \Delta X_2 = \frac{\Delta X_1 + \Delta X_3 + \Delta X_6}{3} \tag{6}$$
$$X_{\text{pred}} = Y_{\text{exp}} + \Delta Y_2 \quad \text{and} \quad \Delta Y_2 = \frac{\Delta Y_1 + \Delta Y_3 + \Delta Y_6}{3}$$

The outcome of this two-dimensional alignment is not a trivial task as it is a function of several factors including the resolution of the experimental gel (the higher, the better) as well as the number and spatial distribution of landmark reference points. It involves working out the transformations that reflect the local distortions of the gel. Several software packages (Melanie, 2004; Z3, 2004;Delta 2D, 2004) currently existing on the market (as well as open source, e.g., **http://open2dprot.sourceforge.net/**) offer robust and flexible spot detection from many popular image file formats coupled with sophisticated statistical analysis and spot-pairing tools.

In the second example, we (arbitrarily) selected and downloaded from SWISS-2DPAGE, a map of human colorectal epithelia cells (Reymond *et al*., 1997). A quantitative measure of the discrepancy between the two data sets can be obtained by using the relative shift (r.s) of a protein spot between experimental and theoretical values.

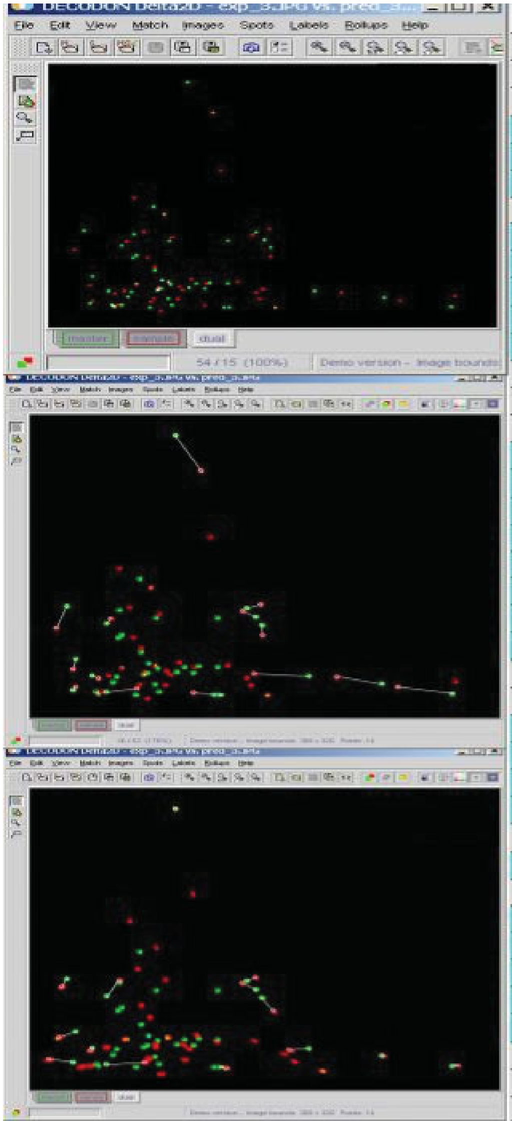
$$r.s = \left[\left(\frac{\Delta pI}{pI_{\text{exp}}}\right)^2 + \left(\frac{\Delta Mw}{Mw_{\text{exp}}}\right)^2\right]^{1/2} \tag{7}$$

where

$$\Delta pI = pI_{\text{exp}} - pI_{\text{pred}} \text{ and } \Delta Mw = Mw_{\text{exp}} - Mw_{\text{pred}}$$

Despite the broad nominal intervals for pI (4–8 pH units) and Mw (0–200 kD), more than 66% of the predicted values have a relative shift less or equal to 0.12 compared to their observed counterpart. However, one must still face the reality of the numerous types of modifications occurring co- and posttranslationally, which can severely alter the electrophoretic mobility of the proteins affected. As can be seen in Figure 5, while relatively small local differences can easily be reconciled, no amount of warping will be able to totally and correctly align a collection of computed pI/Mw data points onto a set of experimentally determined protein spots, without individually identifying and incorporating the aforementioned corrections in the computation of these attributes.

3. TMAP (Tissue Molecular Anatomy Project)



3.1. *Introduction*

By mining publicly accessible databases, we have developed a collection of tissue-specific predictive protein expression maps (PEM) as a function of cancer histological state. Data analysis is applied to the differential expression of gene

Figure 5 (a) Overlap of spots identified in 2D-PAGE map of human colorectal epithelial cell line (in green) and theoretically computed (in red). (b) Several pairs of corresponding experimentally predicted spots are connected to reflect the translations. (c) A global warping attempts to bring the computed value closer to the corresponding observed member of the pair. While in some cases, an almost exact local alignment is achieved, in many instances the differences caused by posttranslational modifications are simply too large to successfully align them. This analysis was carried out using a demonstration version of the Delta-2D package [27]

products in pooled libraries from the normal to the altered state(s). We wish to report the initial results of our survey across different tissues and explore the extent to which this comparative approach may help uncover panels of potential biomarkers of tumorigenesis that would warrant further examination in the laboratory. For the third dimension, we computed inferred gene-product translational expression levels from the transcriptional levels reported in the public databases. A number of studies have explored the feasibility of molecular characterization of the histopathological state from the mRNA abundance reported in public databases. Many potential tissue-specific cancer biomarkers were tentatively identified as a result of mining expression databases. Thus arose the motivation to explore and catalogue correlations across different tissues as a first step toward comparative cancer proteomics of normal versus diseased state. One potential clinical application is uncovering threads of biomarkers and therapeutic targets for multiple cancers.

3.2. Data mining

The Cancer Genome Anatomy Project (CGAP) (Strausberg *et al*., 2000) database of expressed sequence tags (EST), detected in different tissues, is accessible at **http://cgap.nci.nih.gov/**. It can be queried by possible histological state, source, extraction, and cloning method. In the initial construction of queries, selecting the option "ANY" from within all these fields provides an initial overview of the available libraries available. The more restrictive the search, the fewer libraries were selected. Within each library, transcripts are listed along with the number of times they were detected after a fixed number of PCR cycles. Since we were primarily interested in computing protein maps, the gene symbols associated with those ESTs that were clustered to a gene of known function were extracted from UNIGENE (UniGene, 2004). A Perl script performed the cross-reference checking between the two data sets and output a list of gene symbols and corresponding SWISS-PROT/trEMBL accession numbers (AC). The list of resulting AC was input to the pI/Mw tool server that computed the necessary pI (isoelectric focusing point) and molecular mass (Mw) for the mature, unmodified proteins. In the case of a single library, this information was married to the expression-detection counts in the following manner: The number of hits for each EST was first divided by the sum total of sequences within that library to provide a relative expression for each transcript. Finally, a renormalization was carried out by dividing relative expression levels by the maximum relative expression level. In the event a tissue search revealed several libraries fulfilling the requirements of the initial query, to improve the signal-to-noise ratio, the results are first pooled so as to generate a nonredundant list of entries and a more comprehensive expression map for that tissue and corresponding to that histological state. The flow chart is depicted in Figure 6.

3.3. ProtPlot

ProtPlot (Figure 7) is a Java-based data-mining software tool for virtual 2D gels. It was derived from Opensource MAExplorer project (**MAExplorer.sourceforge.net**)

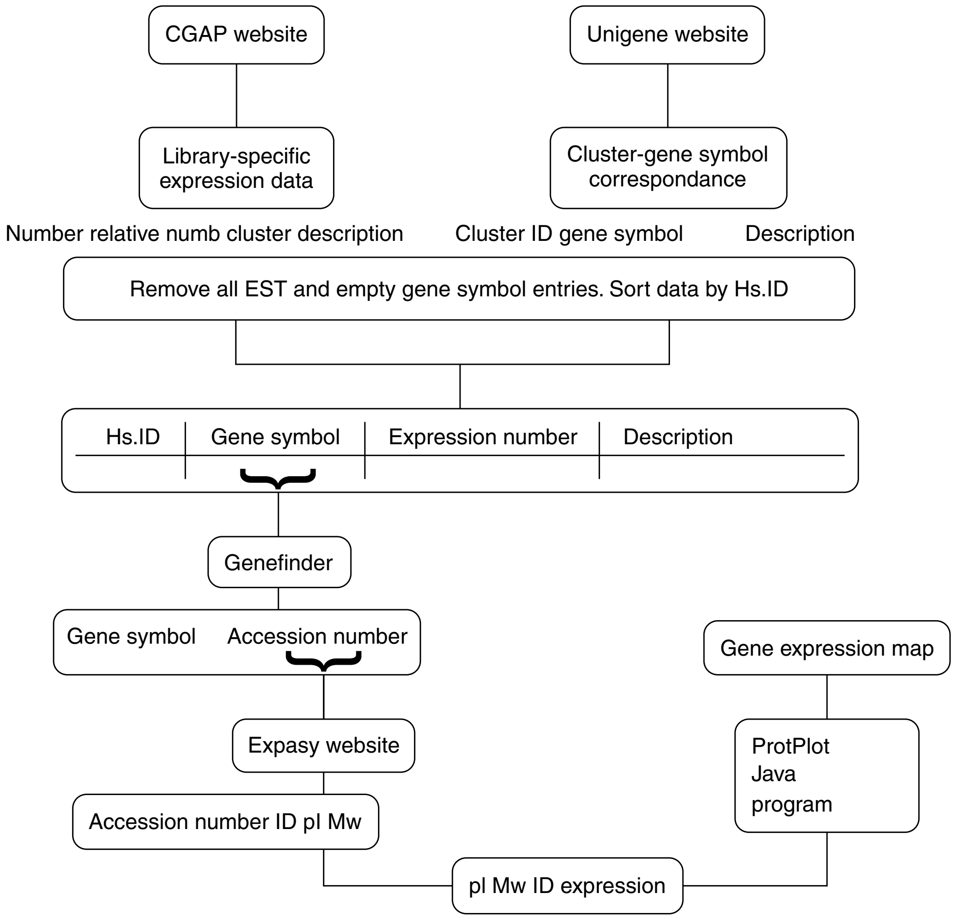

Figure 6 Flowchart describing in detail steps in the computation of expression maps

(Lemkin *et al*., 2000). It may be downloaded and run as a stand-alone application on one's computer. Its exploratory data analysis environment provides tools for the data mining of quantified virtual 2D gel (pIe, Mw, expression) data of estimated expression from the CGAP EST mRNA tissue expression database. This lets one look at the aggregated data in new ways: for example, which estimated "proteins" are in a specified range of (pI, Mw)? Or which sets of estimated "proteins" are up- or downregulated or missing between cancer samples and normal samples? Which sets or "proteins" cluster together across different types of cancers or normals? Here, one may aggregate several different normal and several different cancers as well as specify other filtering criteria.

As is well known, mRNA expression generally does not always correlate well with protein expression as seen in 2D-PAGE gels (Ideker *et al*., 2001). However, some new insights may occur by viewing the transcription data in the protein domain. If actual protein expression data is available for some of these tissues, it might be useful to compare mRNA estimated expression and actual protein

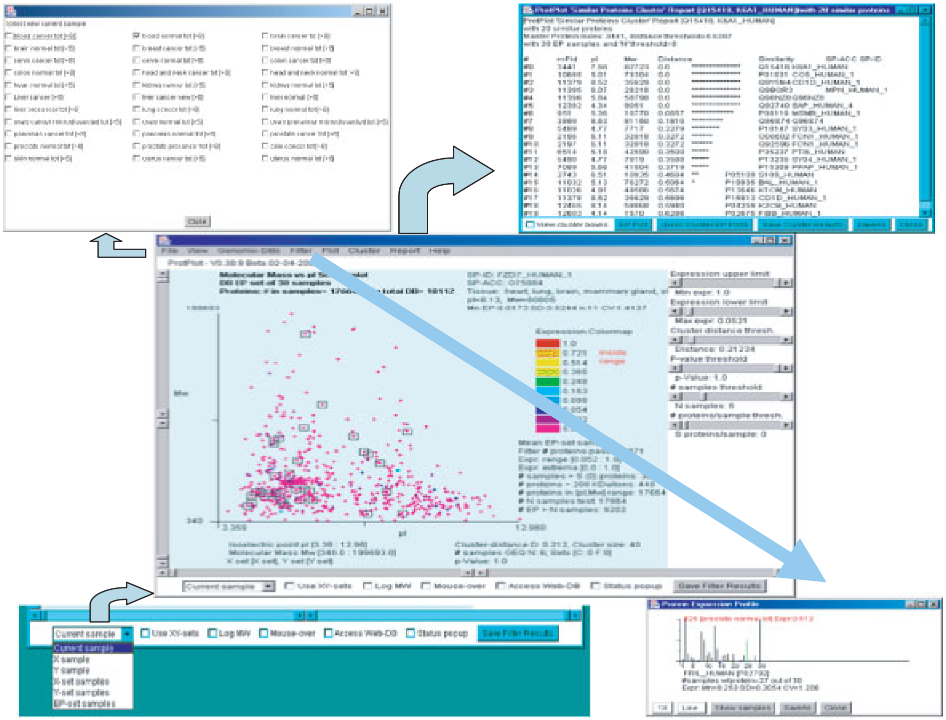

Figure 7 Snapshot of scatter plots from one sample in ProtPlot. It is also possible to create (bottom) an (X vs. Y) scatter plot or (Mean X-set vs. Mean Y-set) scatterplot when the corresponding ratio display mode is set. The following window shows the (Mean X-set vs. Mean Y-set) scatterplot; Tissue and Histology selection, panel b. This may be invoked either from the File menu or the pull-down sample selector at the lower-left corner of the main window. One can at glance obtain the expression profile of proteins or groups of proteins across tissues of choice. The small window illustrates the scrollable list of EP plots sorted by the current cluster report similarity. The spots marked by boxes belong to the same cluster

expression. This tool may help find those proteins with similar expression and those that have quite different expression. This might be useful in thinking about new hypotheses for protein postmodifications or mRNA posttranscription processing.

ProtPlot generates an interactive virtual protein 2D-gel map scatterplot based on the renormalized expression frequencies, derived from the ratios of observed counts versus maximum observed counts for each entry. This "hit" rate can be thought of as a *rough* estimate of gene expression. These ESTs were mapped to SWISS-PROT (**http://www.expasy.ch**) accession numbers and Ids, and the Mw and pI estimates were computed and used as estimates for corresponding proteins in a pseudo 2D-gel.

ProtPlot data is contained in a set of tissue- and histology-specific .prp (i.e., ProtPlot) files described in the data format documentation. These are kept in the PRP directory that comes with ProtPlot after installation. These .prp files can be updated from the ProtPlot Web server **http://tmap.sourceforge.net**.

3.3.1. Using ProtPlot for data mining virtual protein expression patterns

First, one needs to download and install ProtPlot Java program, preferably with the Java Virtual Machine(JVM) as well as the specially formatted CGAP data on a local computer. One starts ProtPlot by clicking on the “ProtPlot Startup” icon if one’s computer supports that (Windows, MacOS-X, etc.) or type ProtPlot on the command line for Unix, Linux, and other systems. Once ProtPlot is started, it loads all the library files (with a .prp extension) present within the PRP directory. The virtual protein data for each tissue is used to construct a Master Protein Index in which proteins will be present for some tissues and not for others. The data is presented in a pseudo 2D-gel image with the estimated isoelectric point (pI) on the horizontal axis and the molecular mass (Mw) on the vertical axis. Sliders on each of the axes allow one control the minimum and maximum values of pI and Mw displayed and thus the Mw versus pI scatterplot zoom region one wants to select. By clicking on a spot in the scatterplot, one will display information on that protein. One can also define that protein as the current protein. The current protein is used in some of the clustering methods, protein specific reports (Expression Profile report), and the Expression Profile plot. If one has enabled the pop-up Genomic-ID Web browser and one is connected to the Internet, it will pop up a Web page from the selected Genomic database for that protein. One then selects various options from the pull-down menus. Some of the more commonly used options are replicated as checkboxes at the bottom of the window.

3.3.2. The Scatterplot display mode

There are two primary types of pseudo 2D-gel (Mw vs. pI) scatterplot display modes (summarized in Table 2) of this derived protein expression data: expression mode or ratio mode. The expression data may be for a single sample (the current sample) or the mean expression of a list of samples (called the expression profile or EP). The ratio data is computed as the ratio of two individual samples called X and Y. Ratio data may alternatively be computed from sets of X samples and sets of Y samples. Generally, one would group a set of samples with similar characteristics together having the same condition (e.g., cancer, normal, etc.). The ratio of X and Y may be single samples in which case the ratio is computed as:

$$\text{ratio} = \frac{\text{expression X}}{\text{expression Y}} \tag{8}$$

Table 2 Summary of the four types of display modes

Display mode	Current sample	Single X/Y	X-set/Y-set	EP-set
Expression	Yes	No	No	No
Single samples ratio	No	Yes	No	No
X-set and Y-set samples ratio	No	No	Yes	No
Mean expression	No	No	No	Yes

where expression X (expression Y) is the expression of corresponding proteins. Alternatively, one may compute the ratio of the mean expression of two different sets of samples (the X set and the Y set). The X and Y sets may be thought of as experimental conditions and the members of the sets being “replicates” in some sense. For example, the X set could be cancer samples and the Y set could be normal samples. The ratio of the X/Y sets for each corresponding protein is computed as

$$\text{ratio} = \frac{\text{mean X-set expression}}{\text{mean Y-set expression}} \tag{9}$$

The following shows a screenshot of one of the (Mw vs. pI) scatterplots when the display mode was set to (X-set/Y-set) ratio mode.

3.3.3. Effect of display mode on filtering, clustering, and reporting

One selects the particular display mode using the Plot menu commands. When one selects a particular display mode, it will enable and disable Filter, View, Cluster, and Report options depending on the mode. For example, one may only use the *t*-test or missing X Y set test if one is in XY-sets ratio mode. One may only perform clustering if one is in EP-set mode. One may change the display mode using the (Plot menu | Show display mode) commands. Alternatively, since it is used so often, there is a checkbox at the bottom of the main window ”Use XY-sets” that will toggle between the XY-sets ratio mode and whatever the previous mode one had set.

3.3.4. Selecting samples

One selects samples for the current sample, X sample, Y sample, X-set samples, Y-set samples, and EP-set samples using a pop-up checkbox list chooser of all samples. For example, one may invoke this chooser for a specific tissue sample one wants to view by using the (File menu | Select samples | Select Current PRP sample) command. For X (Y) data, one invokes the choosers using (File menu | Select samples | Select X (Y) PRP sample(s)) command. One may switch between single (X/Y) and (X set/Y set) mode using the (File menu | Select samples | Use Sample X and Y sets else single X and Y samples [CB]) command.

There is an alternative display called the “Expression Profile” (EP) plot that displays a list of a subset of PRP samples for the currently selected protein. One may also display the scatterplot on the mean EP data for all proteins. The EP samples are specified using the (File menu | Select samples | Select Expression List of samples) command.

3.3.5. Listing a report on sample assignments

One may pop up a report of the current sample assignments for the: current sample single X sample, single Y sample, X sample set, Y sample set, and EP sample set using the (File menu | Select samples | List sample assignments) command.

3.3.6. Assigning the X-set and Y-set condition names

The default experimental condition names for the X and Y sample sets are “X set” and “Y set”. One may change these by the (File menu | Select samples | Assign X (Y) set name) commands.

3.3.7. Status reporting window

There is a status pop-up window that first appears when the program is started and reports the progress while the data is loading. After the data is loaded, it will disappear. One may bring it back at any time by toggling the “ Status popup” checkbox at the bottom of the window. One may also press the “Hide” button on the status pop-up window to make it disappear.

3.3.8. Data filtering

The pseudoprotein data is passed through a data filter consisting of the intersection of several tests including: pI range, Mw range, sample expression range, expression ratio(X/Y) range (either inside or outside the range), t-test comparing the X and Y sample sets, Kolmogorov–Smirnov test comparing the X and Y sample sets, missing proteins test for X and Y sample sets, tissue type filter, protein family filter (to be implemented), and clustering. The filtering options are selected in the Filter menu. If one is looking at the scatterplot in ratio mode, then one may filter by ratio of X/Y either inside or outside of the ratio range. The missing protein test defines missing as totally missing and present as having at least “N” samples present. Note that the t-test and the missing protein tests are mutually exclusive in what they are looking for, so using both results in no proteins being found. Currently, no false discovery rate correction is implemented in the data filters.

3.3.9. Saving filtered proteins in sets for use in subsequent data filtering

One may save the set of proteins created by the current data filter settings by pressing the “Save Filter Results” button in the lower-right of the main window. This set of proteins is available for use in future data filtering using the (Filter menu | Filter by AND of Saved Filter proteins [CB]) command. When one saves the state of the ProtPlot database (Filter menu | State | Save State), it will also write out the save protein sets (saved filtered proteins and saved clustered proteins) in the database “Set” folder with “.set” file name extensions. In the (Filter menu | State | Protein Sets) submenu, there are a number of commands to manipulate protein set files. One may individually save (or restore) any particular saved filtered set to (or from) a set file in the “Set” folder. There are also commands to compute the set intersection, union or difference between two protein set files and leave the resulting protein set in the saved filter set.

Table 3 Available filter options–display modes relationship

Filter name	Current sample	Single X/Y	X-set/Y-set	EP-set
>200 kDa	Yes	Yes	Yes	Yes
Tissue type	Yes	Yes	Yes	Yes
Expression (ratio) range	Expression	Ratio	Ratio	Expression
X/Y (inside/outside) range	No	Yes	Yes	No
(X-set, Y-set) t-test	No	Yes	Yes	No
(X-set, Y-set) KS-test	No	Yes	Yes	No
(X-set, Y-set) missing data	No	Yes	Yes	No
At most (least) N samples	No	No	Yes	Yes
AND of saved cluster set	Yes	Yes	Yes	Yes
AND of saved filter set	Yes	Yes	Yes	Yes

3.3.10. Filter dependence on the display mode

Note that the particular filter options available at any time depend on what the current display mode is. Table 3 shows which options are available for which display modes.

3.3.11. The data-mining "State"

The current data-mining settings of ProtPlot is called the "state". It may be saved in a named startup file called the "startup state file" in the "State" folder. The "State" folder and other folders used by ProtPlot are found in the directory in which one installed ProtPlot. Initially, there is no startup state file. If one saves the state, it creates this file. One may create as many of these saved state files as one wants to. One may change the file and thus save various combinations of settings of samples for the current, X, Y, and expression list of samples. The state also includes the various filter, view, and plot options as well as the pI, Mw, expression, ratio, cluster distance threshold, number samples threshold, p-value threshold sliders, as well as other settings. The saved Filter and Cluster sets of proteins are also written out as .set files in the "Set" folder when one saves the state. Starting ProtPlot by clicking on the ProtPlot startup icon will not read the state file when it starts up. However, if one has saved a state, clicking on the state file or a shortcut to the state file will cause it to be read when ProtPlot starts up. One may save the current state using either the (File | State | Save State) command to save it under the current name, or using either the (File | State | Save As State) command to save it under a new name one may specify. Then one may also change the current state using (File | State | Open Statefile) command.

3.3.12. The molecular mass versus pI scatterplot: expression or ratio

There are two types of scatterplots: expression for a single sample or the ratio of two samples X and Y. The Plot menu lets one switch the display mode. Ratio mode itself has two types of displays: red(X) + green(Y), or a ratio scale ranging between

<1/10 (green) and >10 (red). One may view a pop-up report of the expression or ratio values for the current protein. If "Mouse-over" is enabled, then moving the mouse over a spot will show the name of the protein and its associated data. If mouse-over is not enabled, then clicking on the spot will show its associated data. One may scroll the scatterplot in both the pI and Mw axes by adjusting the end-point scrollbars on the corresponding axes. In addition, the scatterplot can be displayed with a log transform of Mw by toggling the log Mw switch.

The pop-up plots and scatterplot may be saved as .gif image files that are put into the project's "Report" folder. Similarly, reports are saved as tab-delimited .txt text files in the "Report" folder. Because it prompts one for a file name, one may browse the entire file system and save the file in another disk location.

3.3.13. X sample(s) versus Y samples scatterplot

If one is in X/Y ratio mode (single X/Y samples or X-set/Y-set samples), one may view a scatterplot of the X versus Y expression data. The XY scatterplot can be enabled using the (Plot menu | Display (X vs Y) else (Mw vs pI) scatterplot - if ratio mode [CB]) command. One may zoom the scatterplot just as one does for the (Mw vs pI) scatterplot. The proteins displayed are those passing the data filter that have both X and Y data (i.e., expression is > 0.0).

3.3.14. Expression profile plot of a specific protein

An expression profile (EP) shows the expression for a particular protein for all samples that have that protein. The (Plot menu | Enable expression profile plot) pops up an EP plot window and displays the EP plot for any protein one selects by clicking on it. The relative expression is on the vertical axis and the sample number on the horizontal axis. Pressing on the "Show samples" button pops up a list showing the samples and their order in the plot. Pressing on the "nX" button will toggle through a range of magnifications from 1X through 50X that may be useful in visualizing low values of expression. Clicking on a new spot in the (Mw vs. pI) scatterplot will change the protein being displayed in the EP plot. Within the EP plot display, one may display the sample and expression value for a plotted bar by clicking on the bar (which changes to green with the value in red at the top). The EP plot can be saved as a GIF file. One may also click on the display to find out the value and sample. Note: since clustering uses the expression profile, the user must be in "mean EP-set display" mode.

3.3.15. Clustering of expression profiles

One may cluster proteins by the similarity of their expression profiles. First set the plot display mode to "Show mean EP-set samples expression data". The clustering method is selected from the Cluster menu. Currently, there is one cluster method. Others are planned. The cluster distance metric is the "distance" between two proteins based on their expression profile. The metric may be selected in the Cluster Menu. Currently, there is one clustering method: cluster proteins most similar to the current protein (specified by clicking on a spot in the scatterplot or using the Find

Protein by name in the Files menu). It requires one to specify (1) the current protein and (2) the threshold distance cutoff. The threshold distance is specified interactively by the ”Distance Threshold T” slider. The “Similar Proteins Cluster” Report will be updated if one changes either the current protein or the cluster distance.

The cluster distance metric must be computed in a way to take missing data into account since a simple Euclidian distance cannot be used with the type of sparse data present in the ProtPlot database. ProtPlot has several ways to compute the distance metric using various models for handling missing data. The set of proteins created by the current clustering settings can be saved by pressing the ”Save Cluster Results” button in the lower right of the cluster report window. This is available for use in future data filtering using the (Filter menu | Filter by AND of Saved Clustered proteins [CB]) command. When one saves the state of the ProtPlot database (Filter menu | State | Save State), it will also save the set of saved clustered proteins in the database ”Set” folder. One may restore any particular saved clustered set file.

One may bring up the EP plot window by clicking on the ”EP Plot” button and then click on any spot in the scatterplot to see its expression profile. Clicking on the ”Scroll Cluster EP Plots” button brings up a scrollable list of expression profiles for just the clustered proteins sorted by similarity. The proteins belonging to the cluster in the scatterplot with black boxes can be marked by selecting the “View cluster boxes” checkbox at the lower left of the cluster report window. This is illustrated in the following window.

3.3.16. Reports

Various pop-up report summaries are available depending on the display mode. All reports are tab-delimited and so may be cut and pasted into MS Excel or other analysis software. Reports also have a “Save As” button so one can save the data into a tab-delimited file. The default/Report directory is in the directory in which one installed ProtPlot. However, one may save it anywhere on one’s file system. The contents of some reports depend on the particular display mode. This is summarized in the Table 4.

3.3.17. Genomic databases

If one is connected to the Internet and has enabled ProtPlot to “Access Web-DB”, then clicking on a protein will pop up a genomic database entry for that protein. The particular genomic database to use is selected in the Genomic-DB menu.

4. Results and data analysis

Figure 8 depicts the pI/Mw maps computed by our approach for a number of these tissues. They all display the characteristic bimodal distribution that was explained previously as the statistical outcome of a limited, pK-segregated proteomic alphabet. In addition, one can quickly obtain the most significantly differentially expressed gene proteins by computing the tissue-specific charts of the ratios between normal and cancer states (Table 5).

Table 4 Characteristics of available reports as a function of display mode

Filter name	Current sample	Single X/Y	X-set/Y-set	EP-set
Statistics or proteins passing filter	SP-ACC/ID, pI, Mw, expression	SP-ACC/ID, pI, Mw, X/Y, X, Y expr, tissues	SP-ACC/ID, pI, Mw, mnX/mnY, (mn,sd,cv,n) expr for X- & Y-sets, tissues. If using t-test then (dF, t-stat, F-stat). If using KS-test then (dF, D-stat)	SP-ACC/ID, pI, Mw, (mn,sd,cv,n) expr for EP-set, tissues
Expression profiles of proteins passing filter	SP-ACC/ID, expr data EP-set	SP-ACC/ID, expr data EP-set	SP-ACC/ID, expr data EP-set	SP-ACC/ID, expr data EP-set
X & Y sets of missing proteins passing filter	No	No	SP-ACC/ID, (mn,sd,cv,n) for X- & Y-sets	No
EP set statistics of proteins passing filter	No	No	No	SP-ACC/ID, (mn,sd,cv,n) for EP-set
List of samples in current EP profile	{Nbr, sample-name, expression)	{Nbr, sample-name, expression)	{Nbr, sample-name, expression)	{Nbr, sample-name, expression)
List of all sample assignments	Current, X, Y, X-set, Y-set, EP-set	Current, X, Y, X-set, Y-set, EP-set	Current, X, Y, X-set, Y-set, EP-set	Current, X, Y, X-set, Y-set, EP-set

ProtPlot state	State	State	State	State

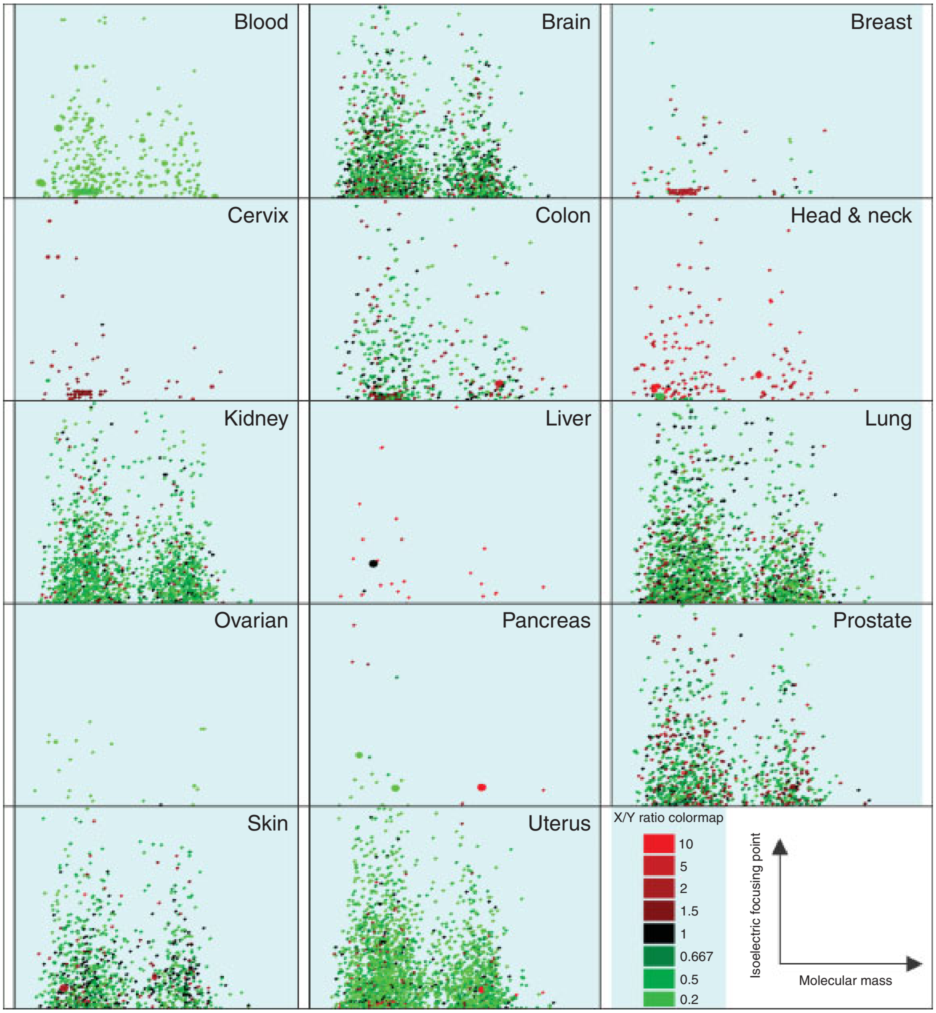

Figure 8 Tissue- and histology-specific pI/Mw interactive maps surveyed to date. The color code for scatter plots of the expression ratios (cancer /normal) is also shown in the figure

A number of proteins detected by the survey described are ribosomal or ribosomal-associated proteins such as elongation factors P04720, P26641 in colon and pancreas. Their upregulation is consistent with an accelerated cancerous cell cycle. Others may turn out to be effective tissue-specific *biomarkers* such as Phosphopyruvate hydratase (P06733 in skin). A third category will turn out to be druggable *targets.* Molecular *switches* that can be the focus of drug design for therapeutic intervention to reverse or stop the disease.

However, identification of useful potential targets requires additional knowledge of their function and cellular location. Accessibility is an obvious advantage. Such isthe case of Laminin gamma-2 (Q13753), the second highest, differentially

Table 5 For each tissue, gene products for which expression profile was the most significantly altered in the cancerous state as compared to the normal state

expressed protein in skin. It is thought to bind to cells via a high-affinity receptor and to mediate the attachment, migration, and organization of cells into tissues during embryonic development by interacting with other extracellular matrix components.

5. Conclusion

To date, the charts for 92 organisms have been assembled and are represented within VIRTUAL2D (**http://ncisgi.ncifcrf.gov/~medjahed**). TMAP (Medjahed *et al*., 2003a) (**http://tmap.sourceforge.net/**) results from the survey of most of the libraries within the CGAP public resource to produce a comprehensive list of putative gene products encompassing normal, cancerous, and when available, precancerous states for 14 tissues. These interactive, knowledge-based proteomics resources are regularly updated and available for download as open source to the research community to generate and explore in the laboratory hypothesis-driven cancer biomarkers.

Short Specialist Review

Disease gene candidacy and ESTs

Mark I. McCarthy
University of Oxford, Oxford, UK

The effort to identify and characterize the genetic variants that underlie susceptibility to common multifactorial traits represents one of the main challenges in biomedical research today. Impressive success in mapping genes underlying Mendelian traits (Peltonen and McKusick, 2001) has, until recently, proved difficult to translate to complex multifactorial traits such as diabetes, heart disease, and asthma (McCarthy, 2004). For such traits, individual predisposition is influenced by variation at many genomic sites, acting in concert with diverse environmental exposures (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2). The contribution made by any one of these factors, considered alone, is generally modest, with the result that detection has only become feasible with the accumulation of large sample sizes and high-throughput technology, coupled with recent advances in genomic information and bioinformatics.

Several different methodologies are used in the search for complex trait susceptibility variants – including linkage analysis and association studies – but all of these, at some stage, require assessment of the relative biological candidacy of a list of genes (Collins, 1995). Such assessments may be based on the full complement of human genes – as in classical candidate gene studies. Alternatively, they may be implemented following a preliminary screen (for example, a genome-wide scan for linkage, or a transcriptional profiling study), which has focused attention on some subset of genes defined in terms of their chromosomal location and/or their transcriptional modulation by pathological and/or physiological perturbation. Typically, the regions identified following a genome-wide linkage scan cover as much as 1% of the genome, and can be expected to contain several hundred genes (Kruglyak and Lander, 1995). Further efforts to map the variant (or variants) responsible typically require further stages of prioritization amongst the genes on this "shortlist", based on the likelihood that each might plausibly be involved in disease pathogenesis (McCarthy *et al*., 2003).

Such prioritization is particularly difficult when, as with most multifactorial traits, the mechanisms underlying disease development are only poorly understood. Transcriptional profiling, proteomic and other novel methods are steadily improving our capacity to identify pathways apparently disturbed during disease development, but it can be difficult to attribute causality. Given these reservations, expression pattern information can play a valuable role in candidate gene prioritization. For many multifactorial traits, there is a reasonable basis for designating the tissues

and/or cell types most likely to be implicated in disease development. By matching this information to the tissue expression profiles of genes of interest, it becomes possible, in principle at least, to highlight putative susceptibility genes.

Ideally, such analyses would benefit from an explicit and exhaustive inventory of the transcriptional repertoire – including patterns of alternative splicing – of every tissue and cell type, basally and in response to physiological and pathological perturbation, and at all stages of development and aging. Despite the rapid accumulation of data from microarray studies and other sources, such a complete view remains some way off. In the meantime, EST (expressed sequence tags) data (and other transcript resequencing data derived from full-length clones or SAGE – serial analysis of gene expression – analysis) can provide some valuable indications of gene expression profiles. The ESTs catalogued in databases such as dbEST (**http://www.ncbi.nlm.nih.gov/dbEST/**) carry information not only on sequence, but on the library from which they were derived, information that typically includes an anatomical location and in some cases associated data on pathology, cell type, and (less so in humans) developmental stage (*see* Article 78, **What is an EST?**, Volume 4).

Two of the main obstacles to the use of such EST data have been overcome in recent years. First, the task of combining multiple EST reads into single transcripts has been tackled by a variety of clustering algorithms (Burke *et al*., 1999; Pertea *et al*., 2003; *see also* Article 88, **EST clustering: a short tutorial**, Volume 4), and more recently, by the availability of an increasingly complete human genome sequence against which ESTs can be aligned, as well as by a move toward sequencing of full-length clones (Imanishi *et al*., 2004). The second barrier to the use of EST data had been the absence of any systematic description of the libraries from which ESTs were derived. For example, transcripts expressed in pancreatic beta-cells might have been present in libraries whose origin was recorded under a range of valid but nonstandardized sobriquets – for example, “pancreas”, “islet”, “endocrine pancreas”, “beta-cell”, “b-cell”, and “insulinoma”. The solution here has been to map all of these descriptions onto controlled terms organized into hierarchical ontologies covering anatomical site and other descriptive dimensions (*see* Article 79, **Introduction to ontologies in biomedicine: from powertools to assistants**, Volume 8), thereby making EST (and related expression) data accessible for database queries. The eVOC system, for example, provides such a systematic description for over 7000 cDNA and SAGE libraries used as sources for expression data in terms of Anatomical Site, Cell Type, Pathology, and Developmental Stage (Kelso *et al*., 2003). eVOC terms have been incorporated within the ENSMART facility at ENSEMBL (**http://www.ensembl.org/Multi/martview**), allowing researchers to readily include expression state – along with chromosomal location and gene function – in their assessments of biological candidacy (Kasprzyk *et al*., 2004).

Nevertheless, several important limitations to the use of such data remain. Most importantly, EST (and other transcript sequencing) data are only available from a sporadic and incomplete range of tissues, with several major tissues (such as fat) poorly represented. In addition, the depth of sequencing varies from tissue to tissue, and even though much EST sequencing has been performed on normalized libraries, for all but a handful, transcript representation is far from being comprehensive. For

related reasons, EST data are semiquantitative at best: SAGE-derived transcriptional data may be more useful when a quantitative view is desired (Cras-Méneur *et al*., 2004).

Transcript sequencing data have proven most useful in the search for susceptibility genes for those diseases where the key pathophysiological events can be confidently localized to a particular tissue, especially where that tissue has a highly specialized function. Obvious examples include many monogenic causes of blindness related to retinal degeneration (Katsanis *et al*., 2002; Sohocki *et al*., 1999), and deafness arising from cochlear pathology (Skvorak *et al*., 1999); in such cases, expression information has contributed significantly to successful gene identification (Sullivan *et al*., 1999). Examples from complex traits are harder to define, not least because it is rarely possible to be so precise about the tissues involved in disease pathogenesis. In the case of type 2 diabetes for example, there are strong grounds for suspecting that fundamental molecular events might occur in a range of tissues (muscle, fat, liver, brain, pancreas): while this information can still help refine a list of positional candidates, the scope for pinpointing one or two key candidates on the basis of expression data alone is clearly modest. One of the few attempts to make systematic use of expression state information for a complex trait relates to Parkinson's disease, where, unusually, the lesional site is well defined (Hauser *et al*., 2003).

The value of EST data as a means to infer the expression distribution of transcripts will undoubtedly diminish with the advent of alternative approaches that are able to deal more effectively with questions of representation and quantification (notably, those using cDNA and/or oligonucleotide microarrays). However, it is important also to recognize the potential limitations of such hybridization-based methods: for example, the danger of cross-hybridization between closely related sequences, and the possibilities for misinterpretation that can result from alternative splicing.

Looking forward, there is no doubt that positional cloning efforts, in monogenic and complex traits alike, will make increasing use of expression state information, along with diverse other sources of data, to assist in the difficult task of assessing the biological candidacy of the long lists of genes that emerge from genome-wide approaches to susceptibility gene identification.

Short Specialist Review

The role of nonsense-mediated decay in physiological and pathological processes

Jill A. Holbrook, Gabriele Neu-Yilik and Andreas E. Kulozik
University of Heidelberg, Heidelberg, Germany
Molecular Medicine Partnership Unit, Heidelberg, Germany

Matthias W. Hentze
Molecular Medicine Partnership Unit, Heidelberg, Germany
European Molecular Biology Laboratory, Heidelberg, Germany

1. Introduction

In eukaryotes, a conserved surveillance pathway known as nonsense-mediated decay (NMD) regulates the abundance of mRNAs containing premature termination codons (PTCs), defined as in-frame stop codons located upstream of the physiological stop codon. PTCs often arise as the result of pathological problems: to name just a few examples, insertions or deletions in DNA that change the open reading frame almost invariably lead to multiple PTCs downstream of the frameshift; deamination of methylcytosine in CG sequences causes transformation of an arginine codon (CGA) into a stop codon (TGA); or splice site mutations may result in the inclusion of an out-of-frame intronic fragment that introduces PTCs. In addition, PTCs can occur in normal transcripts as a result of physiological processes, such as use of alternative open reading frames, presence of UGA codons encoding selenocysteine, or posttranscriptional editing. NMD appears to have evolved as a means both of controlling expression of physiological transcripts containing PTCs and of limiting production of protein from abnormal PTC-containing transcripts. In this article, we describe the mechanism of NMD and briefly discuss its roles in normal cellular function and in some forms of genetic disease.

2. The molecular mechanism of NMD

In order to selectively degrade PTC-containing transcripts, the NMD machinery must distinguish between a normal stop codon and an abnormal one. Both splicing

and translation appear to be critical for this discrimination in mammals. That splicing is involved in PTC recognition is suggested by the fact that NMD-activating termination codons are generally located at least 50 nucleotides upstream of the last exon–exon junction (Figure 1). Such observational evidence has been confirmed by experiments in which insertion of an intron downstream of a physiological termination codon results in transcript degradation, and by showing that intronless PTC-containing transcripts are immune to NMD. Translation is also central to NMD, as demonstrated by a multitude of experiments in which PTC-containing transcripts are stabilized by interference with normal translational mechanisms. Taken together, these data on splicing and translation indicate that a stop codon is judged as normal or abnormal depending on its position relative to exon–exon junctions and that this positional information is shared between the splicing and translational machinery.

On a molecular level, communication appears to occur through a marker deposited at exon–exon junctions during splicing. This marker has been identified as a dynamic assembly of proteins, known as the exon junction complex (EJC), which is deposited in a sequence-nonspecific manner ∼20–24 nucleotides 5′ to every exon–exon junction (Figure 1). The EJC is involved in cellular processes in addition to NMD, and many of its constituent proteins are exchanged or removed before a transcript exits the nucleus. However, as would be expected, at least some components (proteins Y14/MAGOH, RNPS1, and eIF4AIII) persist into the cytoplasm to tag the location of the exon–exon junction. During translation, if no stop codon is located upstream of an EJC marker, the transcript is validated as normal, presumably as a result of removal of the EJC proteins. However, if a stop codon is identified upstream of an EJC complex, the persisting downstream EJC components appear to recruit or retain human NMD proteins known as UPF1, UPF2, and UPF3 (homologs of yeast NMD factors) and other protein factors (Barentsz and P29) involved in NMD, cooperating with them to trigger mRNA degradation. The protein UPF1, in particular, appears to be central in NMD. UPF1 provides a link between translation and termination, since it associates with both ribosomes and release factors. Furthermore, UPF1 is a target of regulation, undergoing an essential cycle of phosphorylation and dephosphorylation mediated by a group of factors known as SMG proteins (homologs of *Caenorhabditis elegans* NMD factors). Exactly how these interactions lead to transcript decay, however, is not yet well understood. Detailed descriptions of the mechanism of NMD, and primary literature references are contained in recent reviews (Schell *et al*., 2002; Singh and Lykke-Andersen, 2003; Wilkinson, 2003; Holbrook *et al*., 2004; Maquat, 2004).

It is important to note that the current mechanistic understanding of NMD is incomplete. Many transcripts do not behave as expected on the basis of the current model (reviewed in Holbrook *et al*., 2004). Furthermore, NMD never reduces transcript levels to zero, and residual mRNA levels usually range from 10 to 30% of wild-type levels. The fate of such residual transcripts is unclear: some evidence indicates that translation occurs, which could potentially result in biologically significant expression of truncated protein (Bamber *et al*., 1999; Donnadieu *et al*., 2003).

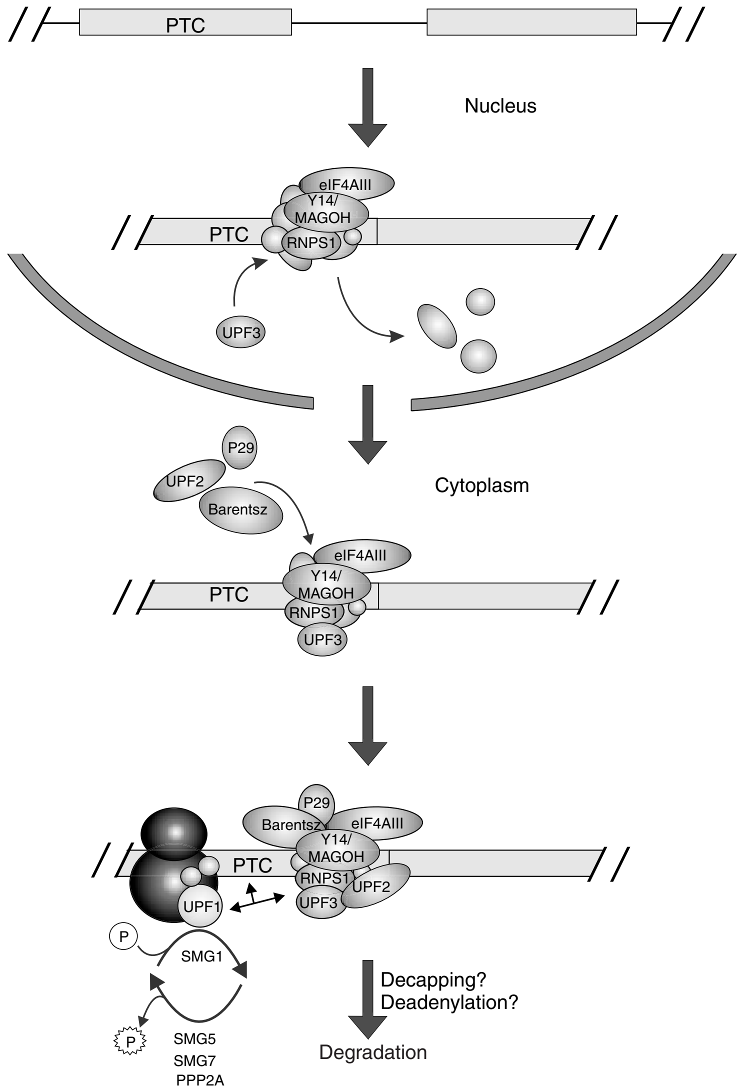

Figure 1 Model of nonsense-mediated decay. (Note: protein–protein interactions as shown in this diagram are meant to be schematic.) During splicing in the nucleus, the exon junction complex (EJC) is deposited in a nonspecific manner 20–24 nucleotides 5′ of exon–exon junctions. The EJC is initially composed of a number of proteins including NMD factors RNPS1, eIF4AIII (also known as Ddx48), and the Y14/MAGOH heterodimer (also known as Rbm8a). During maturation and export of the mRNA and transport through the nuclear pore, the EJC is remodeled and several proteins are released; others, probably including UPF3, are recruited. Both RNPS1 and Y14/MAGOH remain associated with the EJC and accompany the mRNA into the cytoplasm, where other proteins including UPF2, Barentsz (also known as Casc3), and P29 likely join the complex. During translation, the EJCs are thought to be stripped off the mRNA by the translating ribosome, and the mRNA is validated as "error-free" if no EJC is encountered downstream of a stop codon. However, if the translating ribosome (black) encounters a stop codon at least 50 nucleotides upstream of at least one EJC, as demonstrated by the PTC in the figure, NMD is triggered. The protein factor UPF1, which is of central importance in NMD, possibly interacts with the ribosome and release factors (small grey spheres). A cycle of UPF1 phosphorylation (mediated by protein SMG1) and dephosphorylation (involving proteins SMG5, SMG7, and protein phosphorylase 2 A) is essential for NMD to occur. The details of interactions between the ribosome, release factors, UPF1, the PTC, the EJC, and degradation factors are not yet well understood

3. Involvement of NMD in normal gene expression

As described in the Introduction, PTCs may arise in normal transcripts as a result of physiological processes, and one of the important roles of NMD appears to be to help balance the expression of protein or RNA isoforms of these PTC-containing transcripts. To date, the most important and widespread mechanism for introducing PTCs into normal transcripts appears to be alternative splicing (*see* Article 23, **Alternative splicing in humans**, Volume 7). Alternative splicing is potentially capable of producing thousands of PTC-containing transcripts in a normal cell. Unsurprisingly, a large proportion of these transcripts should be eligible to undergo NMD (Lewis *et al*., 2003). In line with these conjectures, a role for NMD in controlling the amounts and/or proportions of splice products has been demonstrated for a number of genes (Sureau *et al*., 2001; Gouya *et al*., 2002; Green *et al*., 2003; Lamba *et al*., 2003; Wollerton *et al*., 2004), most significantly in the case of particular splice factors that appear to autoregulate their abundance through NMD.

Further contributions from NMD to gene expression are likely in other physiologically important systems. For example, in B and T cells, the immunoglobulin and T-cell receptor genes undergo rearrangement, commonly introducing PTCs, and these transcripts are degraded by NMD. Therefore, NMD probably allows protein expression only from successfully rearranged genes, thereby ensuring a fully functioning antigen response (reviewed in Li and Wilkinson, 1998). An intriguing potential role of NMD in telomere physiology is suggested by the involvement in telomere maintenance (Reichenbach *et al*., 2003; Snow *et al*., 2003) of the human homolog of a *C. elegans* NMD protein (Chiu *et al*., 2003). Other physiological processes in which NMD or its components appear to be involved include p53 phosphorylation in response to genotoxic stress (Brumbaugh *et al*., 2004), as well as normal growth and development (Medghalchi *et al*., 2001), production of small nucleolar mRNAs (reviewed in Ruiz-Echevarria *et al*., 1996), and regulation of selenoprotein mRNAs (reviewed in Maquat, 2004).

4. Protective effects of NMD in hereditary and acquired genetic disorders

In addition to its physiological roles, NMD appears to limit production of faulty proteins by degrading pathological (i.e., potentially disease-causing) PTC-containing transcripts. Such transcripts might otherwise result in production of truncated proteins that act in a dominant negative fashion. NMD, therefore, protects against the disease arising from expression of such deleterious mRNAs. Such a protective role of NMD was first demonstrated in β-thalassemia, a condition arising from mutations in β-hemoglobin. Normal erythroid cells contain hemoglobin tetramers composed of two α- and two β-globin subunits. The common recessive form of β-thalassemia is often caused by β-globin mutations that result in production of PTC-containing NMD-sensitive transcripts. These transcripts are degraded by NMD, limiting truncated β-globin synthesis (Hall and Thein, 1994), and the resultant excess of free α-globin, which is harmful to the cell, is

degraded proteolytically. Persons homozygous for these PTC mutations produce little β-hemoglobin and are severely anemic. However, persons heterozygous for such mutations generally synthesize enough β-globin from the remaining normal allele to maintain near-normal hemoglobin levels, and are therefore healthy. Rare NMD-insensitive last-exon PTC mutations, in contrast, give rise to truncated, nonfunctional β-globin that overwhelms the cell's proteolytic system and causes toxic precipitation of insoluble globin chains (Thein *et al*., 1990). The remarkable contrast between asymptomatic heterozygotes with NMD-competent mutations and affected heterozygotes with NMD-incompetent mutations demonstrates that NMD protects most heterozygous carriers from developing dominant β-thalassemia (Kugler *et al*., 1995).

Analogous to the situation described for β-thalassemia, disease-modulating effects of NMD can explain genotype/phenotype relationships in a number of other genetic conditions (Holbrook *et al*., 2004). Furthermore, in acquired genetic disorders, NMD appears to similarly limit expression of truncated, mutant tumor suppressor genes that could give rise to harmful dominant proteins. NMD may thus inhibit cancer development in heterozygotes with a remaining intact tumor suppressor allele (reviewed in Holbrook *et al*., 2004).

5. Therapies in development for treatment of PTC-related disease

In contrast to the protective role of NMD delineated above, NMD can also contribute to disease phenotypes. This occurs when NMD destroys a PTC-containing transcript that codes for a C-terminal truncated protein that, if expressed, would be partly or fully functional. The resultant deficiency in functioning gene product could theoretically be alleviated by preventing NMD-induced transcript degradation. For genetic conditions in which PTC-containing transcripts could produce functional protein – including cystic fibrosis, Duchenne muscular dystrophy, Hurler syndrome, and X-linked nephrogenic diabetes insipidus – interventions to prevent transcript degradation are under development.

The most widely tested approach to allow production of protein from a PTC-mutated mRNA involves the use of aminoglycoside antibiotics. These drugs bind to the decoding center of the ribosome and decrease the accuracy requirements for codon–anticodon pairing, resulting in stop codon readthrough. Therefore, instead of chain termination, an amino acid is incorporated into the polypeptide chain and full-length (although missense-mutated) protein is synthesized. Aminoglycoside treatment has been shown to result in some full-length protein expression and resultant functional improvement in cell lines (Bedwell *et al*., 1997; Barton-Davis *et al*., 1999; Keeling *et al*., 2001), and in most cases, in animal models (Barton-Davis *et al*., 1999; Du *et al*., 2002; Sangkuhl *et al*., 2004). In addition, trials of aminoglycoside therapy have been carried out in humans with PTC mutations, and some promising results have been reported in a subgroup of cystic fibrosis patients in whom treatment resulted in some protein production (Wilschanski *et al*., 2000; Clancy *et al*., 2001; Wilschanski *et al*., 2003). In contrast, two very small clinical studies of patients with muscular dystrophy have been less encouraging,

showing no measurable functional improvement (Wagner *et al*., 2001; Politano *et al*., 2003).

A potentially quite different therapeutic approach is to remove PTCs themselves, rather than interfering with PTC recognition. This can be accomplished in vivo for certain splice site mutations through the use of synthetic oligonucleotide analogs. These oligos hybridize to mutant splice sites or branch point junctions of mutant pre-mRNA, thereby promoting normal splicing and eliminating PTC production that would otherwise occur because of aberrant splicing (Dominski and Kole, 1993). A similar approach has been used in a mouse model to manipulate a PTC-mutated dystrophin mRNA (Mann *et al*., 2001). In this case, antisense oligos were directed toward splice sites flanking a PTC mutation, resulting in in-frame skipping of the affected exon. This treatment removed the PTC, resulting in low-level expression of a shortened but functional dystrophin.

At this time, neither aminoglycoside nor antisense oligo treatment has produced a therapeutically significant benefit in human patients. Of the two, aminoglycoside treatment appears to be the most generally applicable possibility; however, toxicity with prolonged treatment is a concern. A possibly more significant long-term problem could result from general suppression of stop codons, since this might cause accumulation of abnormal mRNAs and abnormal translation of normal mRNAs, potentially leading to production of mutant proteins that interfere with normal cellular functions. Even more significant hurdles remain before it is feasible to treat human patients with antisense oligos, since a systemic delivery method is required, and issues of transfection efficiency, potential immune responses, and side effects must be addressed. Additionally, this treatment would not be general, but would be useful only for cases in which in-frame translation could be maintained without removing essential protein regions. In sum, however, the results from in vitro and in vivo experiments and clinical trials indicate that, at least in principle, functional protein production from PTC-mutated mRNAs is possible.

6. Conclusions

As has become increasingly evident during explorations of its molecular mechanism, NMD is one of the central conserved processes of RNA surveillance. Importantly, NMD acts to control physiological gene expression in a variety of circumstances and is capable of altering expression of both hereditary and acquired genetic diseases. It is therefore necessary to consider the potential action of NMD on transcripts that contain PTCs, regardless of whether PTCs arise in a physiological or pathological context. In specific genetic conditions characterized by protein deficiency, interest is growing in modulating NMD-mediated destruction of transcripts that could otherwise produce functional protein, although development of such treatment strategies is still at an early stage.

Short Specialist Review

Pilot gene discovery in plasmodial pathogens

Jane M. Carlton

The Institute for Genomic Research, Rockville, MD, USA

The scourge of the African subcontinent, the human malaria parasite *Plasmodium falciparum*, causes an estimated 300–500 million cases and 2–3 million deaths each year (Breman *et al*., 2001). Taken together with the most prevalent but rarely fatal species *Plasmodium vivax*, 40% of the world's population is susceptible to infection. Despite such figures, funds for malaria research have lagged behind those for more "Western" diseases such as cancer and heart disease. A malaria vaccine is yet to be produced, and the parasite has developed resistance to many of the antimalarial drugs that are the single line of defense from infection by the parasite. Although much can be blamed on the lack of research funds to counteract this terrible disease, the parasite's complex life cycle that involves multiple tissues in both a vertebrate host and mosquito vector, in conjunction with poor health care services and public infrastructure in many countries where the disease is endemic, have combined to make malaria an intractable part of day-to-day life in the poorest countries of the world.

Despite the limited amounts of funds for research of the *Plasmodium* parasite, malaria researchers were among the very first to understand the power of pilot gene discovery through EST (Expressed Sequence Tag) projects. An EST is a short (300–500 nucleotides) partial sequence of one end of a cDNA clone that provides a sequence tag for a gene (*see* Article 78, **What is an EST?**, Volume 4). In order to achieve high throughput, these sequences are usually only subject to a single pass of sequencing so the error rate can be as high as 5%. However, sequence similarity searches of the tag with public sequence databases can provide a putative identity and function of the cDNA clone, allowing for gene discovery. ESTs can also provide preliminary data concerning stage-specific gene expression, and the capacity for, and process of, alternative splicing. In organisms in which very little genome sequence data is available, EST projects provide an inexpensive, fast, and powerful means for pilot gene discovery, and can increase the number of identified genes in public databases severalfold.

A list of all *Plasmodium* ESTs generated to date is shown in Table 1. The first EST project in a species of *Plasmodium* used cDNA libraries constructed from blood stages of two laboratory clones of *P. falciparum*, from which 1115 ESTs were generated (Dame *et al*., 1996; Chakrabarti *et al*., 1994). Subsequent cDNA libraries

Table 1 Pilot gene discovery in *Plasmodium*. The number of sequenced ESTs present in GenBank's dbEST database are shown for various life-cycle stages

	P. falciparum	*P. vivax*[a]	*P. berghei*	*P. yoelii*

Bs: blood stage; Gm: gametocyte; Oc: oocyst; Spz: sporozoite; Ok: ookinete; Lv: liver; Ah: axenic hepatic.
[a]An additional 20 000 Bs ESTs are currently being generated.

have been constructed from gametocytes, a sexual stage of the parasite (Li *et al*., 2003), and from blood stages of other laboratory lines utilizing different cDNA library construction techniques to enhance full-length cDNA clones (Watanabe *et al*., 2002). Projects to generate additional good-quality cDNA libraries from a variety of *P. falciparum* stages are ongoing, although they are somewhat hampered by the intractability of the *P. falciparum* life cycle, which cannot be completed in a laboratory setting and which limits the amount of biological material available for certain life stages, in particular, the mosquito and liver stages. The problem of limited starting material has also hindered the construction of good-quality cDNA libraries of *P. vivax*. Unlike *P. falciparum*, no continuous culture system has been developed for the maintenance of the blood stages of *P. vivax*, and researchers have been restricted to using blood samples from patients to construct cDNA libraries for sequencing (Merino *et al*., 2003). ESTs from several other *Plasmodium* species have also been generated (Table 1). Two species of rodent malaria, in particular, *Plasmodium berghei* (Carlton *et al*., 2001a; Matuschewski *et al*., 2002; Srinivasan *et al*., 2004; Abraham *et al*., 2004) and *Plasmodium yoelii* (Suzuki *et al*., 1997; Kappe *et al*., 2001; Carlton *et al*., 2002), have significant amounts of EST data from many different life stages. Rodent species of malaria are used as in vivo models to study the human malaria parasite, since they share very many biological characteristics, and provide an analogous system with which to compare and contrast biological mechanisms.

The total number of ~50 000 ESTs generated for the *Plasmodium* genus may seem a rather insignificant number in the light of other organisms for which hundreds of thousands of ESTs exist (e.g., human, mouse, zebrafish). This is because there are several hurdles that must be overcome in order to generate good-quality cDNA libraries from different life stages of the malaria parasite that are amenable to high-throughput sequencing. First, as alluded to above, parasite material from most developmental stages is problematic to obtain in large quantities. In vitro cultivation of some stages of a few species is possible (Schuster, 2002), but in the majority of cases, in vivo material must be dissected and extracted. Second, methods to separate parasites from their host cells are necessary to prevent contamination of the parasite DNA and RNA by host nucleic acids. This is especially important since vertebrate and mosquito genomes are many fold larger

than the ~25-Mb *Plasmodium* genome, so even small amounts of contaminating host material will result in a host-biased library. Several methods, such as filtration through CFll cellulose, ultracentrifugation through Hoechst Dye 33258-CsCl, and biomagnetic separation have been tried and tested (Carlton *et al*., 2001b). Finally, the genomes of *P. falciparum*, *P. vivax*, and the four rodent malaria species show an extreme (AT) bias in their genome sequence. Coding regions are typically 70–80% (AT) and can contain tracts of poly(A) and poly(T) sequence. This can have important consequences in libraries generated by the conventional method of oligo(dT) priming at the 3′-end of mRNA, since priming may occur at regions other than the poly(A) tail. Moreover, highly (AT)-rich DNA is known to be unstable when cloned into *E. coli*, resulting in loss of insert DNA and chimeric clones that can lead to such libraries being nonrandom.

All of the *Plasmodium* ESTs mentioned here are available for downloading and searching through public EST databases such as GenBank's dbEST. Many are also available in custom *Plasmodium* databases, of which there are several. "Full-Malaria" (Watanabe *et al*., 2004) is a database of full-length-enriched cDNAs of *P. falciparum* and *P. yoelii*, which have been mapped to the full-genome sequences of both species. "ApiEST-DB" (Li *et al*., 2004) provides access to EST data from several protozoan parasites in the phylum Apicomplexa, including *Plasmodium*. This relational database can be used for gene model validation, identification of alternative splicing, and identification of phylogenetically conserved sequences. "PlasmoDB" (Bahl *et al*., 2003), the official database of the malaria parasite genome projects, also contains some of the *Plasmodium* EST datasets mentioned here. Finally, the "TIGR Protist Gene Indices" (Quackenbush *et al*., 2001) contains EST data from 15 species of protist including species of *Plasmodium*. The database provides consensus sequences of clustered ESTs and a means of identifying orthologous genes across multiple eukaryotic organisms. The methodology behind EST clustering is explained elsewhere (*see* Article 88, **EST clustering: a short tutorial**, Volume 4).

To what uses have the *Plasmodium* ESTs been put besides pilot gene discovery? A few examples are given here. A study to construct the proteomes of three *Plasmodium* species used several thousand ESTs in conjunction with all known *Plasmodium* genes in GenBank, to compare protein content between the species (Carlton *et al*., 2001a). The *P. yoelii* EST dataset has been used in conjunction with a secondary database of clusters of orthologous groups (COGs) to identify ESTs that remain uncharacterized but have matches to COG proteins, and therefore represent candidates for further protein characterization (Faria-Campos *et al*., 2003). Using the novel technique of subtractive hybridization, *P. berghei* cDNA libraries enriched for genes expressed in ookinetes (Abraham *et al*., 2004) and oocysts (Srinivasan *et al*., 2004) have been generated, and ESTs from these libraries have provided initial insight into *Plasmodium* development in the mosquito. Analysis of multiple ESTs of the same gene have revealed unique features of malaria parasite transcripts, such as the presence of multiple transcription start sites for many genes, and the long length of the 5′ untranslated region (Watanabe *et al*., 2002). And finally, the value of EST data has been emphasized recently with the publication of the genome sequences of two *Plasmodium* species (Carlton *et al*., 2002;

Gardner *et al*., 2002), which relied significantly upon the EST data for training gene finder software and for gene model verification.

The generation of further *Plasmodium* EST data continues, in particular, from other life-cycle stages of *P. falciparum* and other species such as *P. vivax*. In addition, although the *Plasmodium* EST datasets have more than proven their worth, the continued development of full-length cDNA library construction technology is promising and has the potential to produce better gene expression data for the annotation of the six additional *Plasmodium* genome sequencing projects that are currently in progress.

Manufacturing EST libraries

Marcelo B. Soares and Maria F. Bonaldo
Children's Memorial Research Center, Northwestern University, Chicago, IL, USA

1. Introduction

Several articles and book chapters have been written on the topic of constructing cDNA libraries for large-scale production of expressed sequence tags (ESTs), including detailed discussions of existing methodologies and step-by-step protocols (Bonaldo *et al.*, 1996; Soares, 1994; Soares and Bonaldo, 1998; Soares and Bonaldo, 2002). Hence, rather than describing specific procedures, we identify problems that occur systematically in the manufacturing of EST libraries, discuss their cause and outcome, explain how they may be diagnosed, and indicate how they may affect analysis and interpretation of EST data.

2. The value of ESTs as tools for transcriptome analysis

ESTs are single-pass sequence reads derived from 5′ (5′ EST) and 3′ (3′ EST) ends of directionally cloned cDNAs (*see* Article 78, **What is an EST?**, Volume 4). Since EST libraries, that is, cDNA libraries utilized for production of ESTs, are almost invariably composed of oligodeoxythymidylate- (i.e., oligo(dT)-) primed, directionally cloned cDNAs, 3′ ESTs typically span the 3′ terminal noncoding exon of mRNAs, while 5′ ESTs encompass 5′ noncoding, coding and/or 3′ noncoding exons, depending on whether they are derived from full-length or truncated cDNAs (Soares and Bonaldo, 2002).

Although principally utilized for large-scale gene discovery, ESTs may reveal alternative RNA processing (splicing and polyadenylation), intronic expression, gene fusions resulting from chromosomal rearrangements, internal exon deletions, exon extensions, antisense transcription, and so on (Bonaldo *et al.*, 2004; Brentani *et al.*, 2003; Dimopoulos *et al.*, 2000; Hackett *et al.*, 2004; Hillier *et al.*, 1996; Kochiwa *et al.*, 2002; Okazaki *et al.*, 2002; Rosok and Sioud, 2004; Scheetz *et al.*, 2004a; Verjovski-Almeida *et al.*, 2003). Nevertheless, their value relies on the quality of the cDNA library from which they originate. Indeed, cDNA libraries of inadequate quality often yield artifactual ESTs that if not recognized may engender erroneous conclusions (e.g., cDNA chimeras: a cDNA containing sequences derived from more than one mRNA). Despite curation efforts, public

databases (*see* Article 80, **EST resources, clone sets, and databases**, Volume 4) do contain a significant number of artifactual ESTs (Adams *et al*., 1991).

3. Manufacturing EST libraries: a brief overview

Like some other laboratory procedures in molecular biology, the manufacturing of an EST library is indeed an art. The mere utilization of a well-established and proven protocol simply does not suffice as a guarantee of successful outcome. Certainly not, unless – and on occasion, even if ... – performed by an adept and meticulous experimentalist, who notably understands the biochemistry underlying each reaction in the process. Ultimately, the quality of an EST library is circumscribed by that of the RNA template from which it originates. Cytoplasmic mRNA is the template of choice (Carninci *et al*., 2002), but because it cannot always be obtained, total cellular poly(A)$^+$ RNA is more often utilized.

Although every reaction contributes to the quality of an EST library, first-strand cDNA synthesis is arguably the most critical step, and where problems often arise. First-strand cDNA synthesis can be initiated at the 3′ terminal poly(A) tail using an oligo(dT) primer, or at multiple sites within a transcript, simultaneously, using random primers. Although coding and 5′ noncoding regions are better represented in random primed- than in oligo(dT)-primed libraries, the lack of cloning directionality and the presence of multiple nonoverlapping truncated cDNAs make random primed libraries disadvantageous for large-scale transcript discovery.

Cloning directionality can be achieved by the inclusion of a restriction endonuclease site, such as *Not I*, in the oligo(dT) primer utilized for synthesis of first-strand cDNA (i.e., 5′ *Not I* – $[dT]_{18}$ 3′). Digestion of double-stranded cDNAs with *Not I* thus enables orientation-specific ligation to the cloning vector (Bonaldo *et al*., 1996). To maximize cloning efficiencies, cDNAs are first ligated to a synthetic adapter molecule (e.g., *Eco RI* adapter) and then digested with *Not I*. To avoid digestion at internal *Not I* sites, methyl(dCTP) may be incorporated during first-strand cDNA synthesis (Carninci *et al*., 2000); *Not I* is sensitive to CpG methylation. It is noteworthy that there are many *Not I*-truncated ESTs in public databases, predominantly derived from nonmethylated cDNAs.

The oligo(dT) primer utilized for synthesis of first-strand cDNA may be designed to contain a library-specific sequence tag, typically comprising 6–10 nucleotides, between the restriction site and the $(dT)_{18}$ sequence: 5′ *Not I* – library tag – $(dT)_{18}$ 3′. This is advantageous because it enables the identification of library/tissue of origin of ESTs derived from pooled libraries (Gavin *et al*., 2002; Laffin *et al*., 2004; Scheetz *et al*., 2004a,b). Library-specific tags have also proven invaluable to uncover library mix-ups and clone contaminations.

4. Commonly observed problems in EST libraries

A wide range of problems has been observed in EST libraries, some simple others complex (Soares, 1994; Soares and Bonaldo, 1998). Simple problems not uncommon in EST libraries include the presence of short cDNAs, cDNAs with long

poly(A/T) tails, cDNAs consisting exclusively of poly(A/T) tails, chimeric cDNAs, cDNAs derived from contaminating endogenous or exogenous DNA or RNA (e.g., bacterial DNA, nuclear DNA and RNA), and truncated cDNAs resulting from digestion at internal *Not I* sites. These problems can be greatly minimized by abiding to a few measures. First, the RNA template for synthesis of first-strand cDNA should be predigested with *RNAse*-free *DNAse I* to destroy any contaminating DNA that might otherwise be cloned. Second, a reliable size selection procedure should be utilized to exclude small cDNA fragments and excess adapter molecules. This will not only reduce the representation of clones with short inserts but will also lower the frequency of chimeric cDNAs in the library – small cDNAs often remain unaccounted in the calculations to estimate the mass of cDNA synthesized and thus determine the amount of *Eco RI* adapter and, subsequently, of cloning vector in the ligation reactions. If the amount of cDNA is underestimated, not sufficient adapter molecules are added to the reaction and chimeric cDNAs are generated. Third, methyl(dCTP) should be incorporated during first-strand cDNA synthesis if, subsequently, cDNAs are digested with a restriction endonuclease that is sensitive to CpG methylation. This will minimize the representation of truncated cDNAs resulting from digestion at such internal restriction sites. Fourth, the cloning vector, often a plasmid, should be purified from any contaminating bacterial DNA that might otherwise be cloned.

Complex problems commonly observed in EST libraries, on the other hand, cannot be as easily avoided. However, they can be minimized, and most importantly, they must be recognized in order not to cause misinterpretation of EST data. Complex problems fall into two groups: those that affect transcript representation in the library, either partially or totally, and those that have an effect on cloning directionality.

5. Problems that affect transcript representation in the library

5.1. *Problems that compromise representation of a specific region of a transcript*

The presence of an A-rich stretch at a relatively short distance (i.e., $\leq$250 nucleotides) from the 3′ terminal poly(A) tail may compromise representation of the region of the transcript between the internal A-rich sequence and the poly(A) tail. This is due both to unintended priming at the internal A-rich sequence with the 5′ *Not I* – library tag – $[dT]_{18}$ 3′ oligonucleotide, and to the fact that first-strand cDNA synthesis initiated at the 3′ terminal poly(A) tail ends at the internal priming site. The small 3′ terminal cDNA fragment generated during second-strand synthesis is eliminated during cDNA size selection. Such a problem is often observed in transcripts bearing an *Alu* repeat, in the sense orientation, within the 3′ noncoding region – full-length *Alu* transcripts contain an oligo(A) tail at the 3′ terminus. This is significant considering that Alu repeats occur in noncoding exons of approximately 10% of human mRNAs (Deininger and Batzer, 2002; Weiner, 2002). Internal priming may be minimized, but not eliminated, by an increase in the temperature of the reverse transcription reaction.

Similarly, the occurrence of a *Not I* site within a transcript may compromise library representation of the region localized between the *Not I* site and the 3′ terminal poly(A) tail – the 3′ terminal *Not I* cDNA fragment, extending from the *Not I* site in the primer (5′ *Not I* – library tag – $[dT]_{18}$ 3′) to the internal *Not I* site in the cDNA, cannot be cloned. Hence, representation of such transcripts will be limited to the region between the internal *Not I* site and the EcoRI adapter at the 5′ end of the cDNA. Such *Not I*-truncated cDNAs give rise to ESTs lacking the terminal (dA/dT)-tail. As previously discussed, this problem is mostly observed when dCTP, instead of methyl(dCTP), is used in the synthesis of first-strand cDNA.

5.2. *Problems that compromise representation of an entire transcript*

The presence of an oligo(U) stretch in the 3′ noncoding region may abrogate representation of a transcript, if it occurs within ≤250 nucleotides from the poly(A) tail. This is presumably due to the formation of a stem-loop structure in which the 3′ terminal (A) residues of the poly(A) tail of the RNA are base paired with the complementary (U) residues of the internal (U)-rich sequence. As a result, first-strand cDNA synthesis is simultaneously initiated at two sites: along the looped poly(A) tail, primed by the 5′ *Not I* – library tag – $[dT]_{18}$ 3′ oligonucleotide, and within the internal (U)-rich sequence, self-primed by the 3′ terminal (A) residues of the poly(A) tail of the RNA. The former results in a short product that is eliminated during cDNA size selection. The latter product cannot be cloned because it lacks appropriate *Not I* – *Eco RI* ends. Hence, such a transcript would not be represented in the library.

This scenario may happen with transcripts bearing an *Alu* repeat in the antisense orientation, particularly if the element is truncated. Since the full-length *Alu* repeat is approximately 300 nucleotides long, the occurrence within a transcript of a full-length copy of an *Alu* repeat in the antisense orientation is more likely to result in partial representation, rather than obliteration, of the transcript – the cDNA product corresponding to the region of the transcript extending from the poly(A) tail to the internal oligo(U)-tail of the *Alu* would be larger than 300 bp and thus escape exclusion during cDNA size selection.

6. Problems that affect cloning directionality

One should be cautious using ESTs as evidence of transcription orientation because not all cDNAs in a directional library are cloned in the intended orientation. For example, when utilizing ESTs for computational identification of putative Natural Antisense Transcripts (Kiyosawa *et al*., 2003; Lavorgna *et al*., 2004; Rosok and Sioud, 2004; Yelin *et al*., 2003).

While scrutinizing large numbers of ESTs, we have identified a problem in the manufacturing of EST libraries that causes cDNAs to be cloned in the wrong orientation. On occasion, the *Not I* site in the 5′ *Not I* – library tag – $[dT]_{18}$ 3′ oligonucleotide is destroyed during cDNA synthesis, thus generating a 5′ phosphate

terminus that can be ligated to an *Eco RI* adapter – presumably due to genuine or contaminating nucleolytic activity present in an enzyme utilized in the synthesis of double-stranded cDNA. Hence, the primer for first-strand cDNA synthesis should contain at least five nucleotides 5′ to the *Not I* site. This will not only protect the integrity of the restriction site but will also contribute to increase cleavage efficiency at an otherwise terminal *Not I* restriction site.

Two possible outcomes can be envisioned, should such an event occur. The first, and most likely, is that the cDNA cannot be cloned because it has *Eco RI* adapters at both 5′ and 3′ ends. The second, invoking the presence of an internal *Not I* site in a cDNA, is that one of the two truncated cDNAs generated upon digestion with *Not I* can only be cloned in inverted orientation: that is, the 5′ *Not I* – 3′ *EcoRI* fragment encompassing the region from the internal *Not I* site to the 3′ *Eco RI* adapter. It is noteworthy that the latter clone would give rise to a 5′ EST with an oligo(dA) tail at the 5′ end.

EST clustering: a short tutorial

Winston A. Hide
South African National Bioinformatics Institute, University of the Western Cape, Bellville, South Africa

1. Introduction

Expressed sequence tags (ESTs) have been a cornerstone of gene discovery since their large-scale implementation in the early 1990s (Adams *et al*., 1991). By utilizing the existing sequencing technology, the concept of single pass reads "trapping" a fragment or tag of expressed genome sequence has been applied simply and with success across hundreds of species. Once generated, ESTs have potential information that can only be realized by subsequent exhaustive processing in an attempt to reconstruct the transcripts from which they have been sampled.

2. What is an EST cluster?

A cluster is fragmented, EST data and (if known) gene sequence data, consolidated, placed in correct context, and indexed by gene such that all expressed data concerning a single gene is in a single index class, and each index class contains the information for only one gene (Burke *et al*., 1999). Owing to the fragmented nature of EST reads, it is worthwhile to attempt to organize the reads into assemblies that provide a consensus view of the sampled transcripts. In order to reconstruct a true consensus reflection of the sampled parent transcripts, it is necessary to address several complex problems: Should clustering be attempted at the gene locus level or at the parent transcript level? Completeness and availability of parent genome sequence is a major factor. If clustering is at the gene level, how are the limits of the transcribed gene defined? Recent studies indicate that several forms of transcript can be generated from a single locus (Hide *et al*., 2001; Burke *et al*., 1998; Modrek *et al*., 2001; Pospisil *et al*., 2004) and that antisense RNAs and possibly other forms of RNAs revealed in recent tiling path studies can overlap their expression over the same sets of genomic nucleotides (Dahary *et al*., 2005; Hayashizaki and Kanamori, 2004, Kapranov *et al*., 2002). Understanding of transcript biology is still insufficient to allow for "true" transcript clusters to be well defined. If clustering is performed at the transcript level, overlapping transcripts that share the same genic locus must be qualified. Given a definition of overlap, transcript reconstruction can be performed via simple assembly, but the assemblers used must be able to handle unknown forms of transcript diversity that may include alternate

splice forms, identical exons from different chromosomal loci or other paralogous sequences sharing overall high sequence identity. Overclustering can also occur as a result of chimeric clones, shared vector sequence, and uncharacterized or poorly masked repeats. Underclustering can occur as a result of highly abundant transcripts, overstringent clustering parameters, or fragmentation of assemblies. Genome assemblers are designed for shotgun genome assembly, where there are several reads covering the same nucleotide. For EST assembly, the density of coverage varies directly according the level to which the nucleotide in question has been expressed and the degree to which it is sampled. It is fruitful to utilize pipelined approaches that combine algorithms to maximize the content and quality of the reconstruction of transcripts from the assembly of clusters.

3. The EST clustering process

The aim of EST clustering is simply to incorporate all ESTs that share a transcript or gene parent to the same cluster. There is usually a requirement to assemble the clustered ESTs into one or more consensus sequences (contigs) that reflect the transcript diversity, and to provide these contigs in such a manner that the information they contain most truly reflects the sampled biology. The process is confounded by a lack of absolute knowledge of the true biology.

Systems that have broad acceptance and are widely distributed or widely accessible include SANBI at University of Western Cape's StackPACK, TIGR's TGI Clustering tools (TGICL), and NCBI's Unigene (Table 1). Commonly, these systems share an overall approach, but differing in choice of algorithms used, reconstruction aims, and coverage of transcript diversity. The systems perform a preprocessing step that screens out vector, repeat, and low-complexity sequences. A database of vectors and repeats is passed across each EST, and where matches above a certain threshold occur, the matched nucleotides are substituted for a null character such as an "N" (Bedell *et al*., 2000). Masked ESTs are initially

clustered by a process of initial all-against-all comparison. The resulting clusters are assigned by some form of sequence identity above a threshold, either at the level of shared word multiplicity (StackPACK's D^2 pseudometric) or sequence overlap (TIGR, NCBI). Assembly of clusters is strongly biased by the choice of assembler. Although Liang *et al*. performed a comparative analysis of the suitability of use of CAP3 (Huang and Madan, 1999; Liang *et al*., 2000), they did not take into account the flexibility of the chosen assembler for the incorporation of alternate splice forms into the generated consensus sequences. Choice of assembler is affected by the desired result. Features of the different systems are as follows: StackPACK, performs initial clustering on the basis of shared word multiplicity followed by assembly and consensus processing steps (Miller *et al*., 1999). The system is suitable for providing reliable capture of transcript diversity such as alternate splicing within gene-based clusters. StackPACK utilizes a more relaxed initial clustering, and also a more flexible assembler (PHRAP) generating more contigs per cluster, but incorporating more alternate splicing events. Less-stringent clustering, however, requires that there be a consensus management step to sort out the relationships of the contigs generated within clusters. TGICL is another broadly used procedure that combines EST clustering based on sequence similarity and subsequent transcript assembly (Quackenbush *et al*., 2001; Pertea *et al*., 2003). Initial clustering is performed by a modified version of NCBI's *megablast*, and the resulting clusters are then assembled using the CAP3 assembly program. Larger numbers of contigs in separate clusters are generated by this procedure than in StackPACK. More recently, graph-based approaches to transcript reconstruction have been developed that address the potential isoform diversity of reconstructed transcripts as a graph (Heber *et al*., 2002; Xing *et al*., 2004). The most well known clustering system is that utilized by NCBI for the frequently updated Unigene series

of databases (**http://www.ncbi.nlm.nih.gov/UniGene**). Unigene is unique amongst these systems in that it does not attempt to reconstruct transcripts but rather attempts to define their cluster membership on the basis of NCBI data. Methods to deal with error vary widely amongst all systems. A common example of error in clustering is that of incorrect clone joining. The process of EST manufacture usually requires that a clone be sequenced from one or both ends. As a result of this experimental design, it is possible to join 5′ and 3′ ESTs that originate from the same cluster that share a parent clone. However, missannotations can result in the spurious formation of superclusters, requiring that more than one pair of ESTs sharing parent clones be required to join two clusters. Links to appropriate EST resources and information are provided in Table 2.

Basic Techniques and Approaches

Using UniGene, STACK, and TIGR indices

Alan G. Christoffels

Temasek LifeSciences Laboratory, National University of Singapore, Singapore

1. Introduction

Expressed sequence tag (EST) (*see* Article 78, **What is an EST?**, Volume 4) sequencing and analysis represent a critical tool in the identification of genes and for annotation of genomic sequence despite the increase in sequenced genomes. However, the challenge in using EST data is to assign an EST to a gene without prior knowledge of the EST's origin (*see* Article 88, **EST clustering: a short tutorial**, Volume 4). This challenge has been met by three research organizations, namely, (1) National Center for Biotechnology and Information (NCBI), (2) South African National Bioinformatics Institute (SANBI), and (3) The Institute for Genome Research (TIGR) through the development of UniGene, STACK, and TIGR gene indices respectively. The gene indices represent processed EST and mRNA transcripts, where the transcripts are grouped or clustered into nonredundant transcripts associated with distinct gene loci. Each of these gene indices shares a common framework of data cleaning, clustering, and assembly, with additional modifications to meet a specific goal. A comparison among the gene indices' protocols is presented as a flowchart (Figure 1) followed by information that can be gleaned from the user interface designed for each of the gene indices (Figures 2–4).

2. UniGene

The UniGene builds protocol implements: (1) a transcript-based approach utilizing ESTs and mRNAs exclusively and (2) a genome-based approach where transcripts are mapped to genomic sequences to identify gene loci (see Figure 1 for the transcript-based approach; Pontius *et al*., 2003). UniGene data can be queried using a UniGene identifier, GenBank EST accession number, cDNA library, or a chromosome location (Wheeler *et al*., 2003). The retrieved UniGene record will have cross-links to databases, including ProtEST for protein similarities, Digital Differential Display for expression profiles, and Homologene to identify putative orthologous relationships (Figure 2). Notice the absence of assembly information due to the inclusion of nonoverlapping ESTs that share a cloneID (Figure 1). Queries against the UniGene database can be more specific by restricting the query

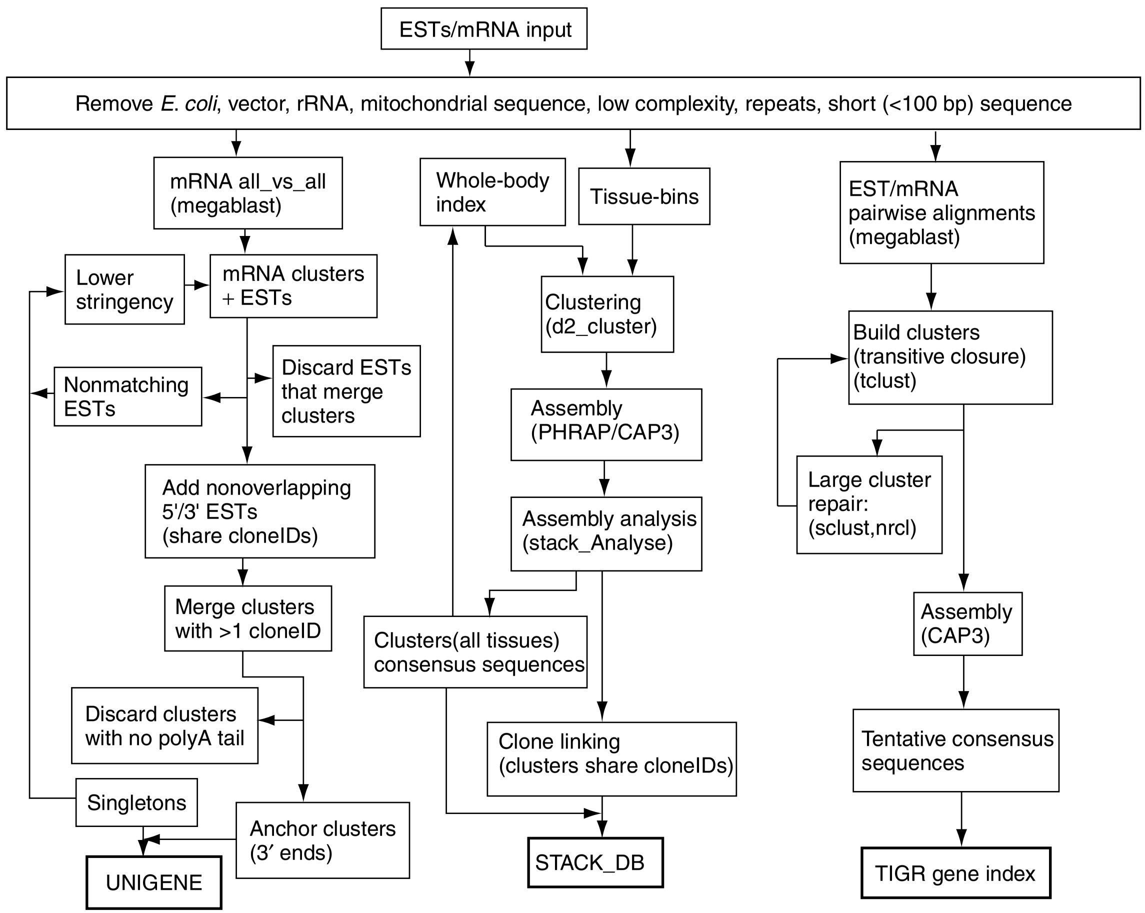

Figure 1 Comparison of the clustering approaches implemented in UniGene, STACK, and TIGR gene indices. The clustering protocol begins with a data-cleaning step followed by pairwise alignment clustering of ESTs (UniGene and TIGR) or word-based clustering (STACK). EST clusters are assembled using PHRAP or CAP3 (STACK and TIGR respectively) and further assembly assessment carried out in STACK processing

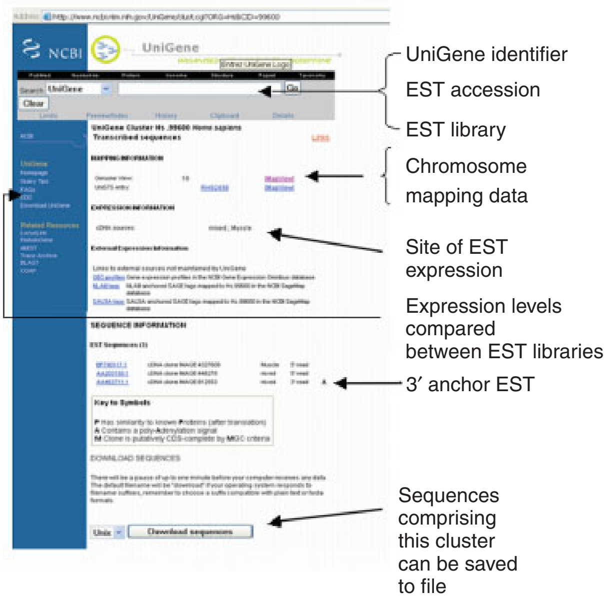

Figure 2 UniGene cluster information as displayed on the NCBI website. UniGene-id Hs.99600 was used to retrieve the cluster report

to specific fields, for example, searching for clusters containing one to ten ESTs using "1:10[ESTC]". Additional field restriction terms are available from the NCBI website at **http://www.ncbi.nlm.nih.gov/UniGene/query_tips.html**.

3. Sequence tag alignment and consensus knowledgebase (STACK)

STACK implements a loose clustering system, d2_cluster (Burke *et al*., 1999), which does not rely on pairwise alignment but instead assesses the composition and multiplicity of words within a sequence (Figure 1). This approach allows for the capture of otherwise discarded low-quality sequence with the result that the integrity of each cluster is assessed by error-checking tools (Figure 1; Miller *et al*., 1999).

STACK allows the user to explore 14 tissue categories, a disease category, and a whole-body index. The STACK database can be viewed via the Web at **http://www.sanbi.ac.za/stacksearch.html** using a sequence as input into a BLAST engine. The BLAST results are hyperlinked to the STACK viewer, which allows for extraction of detailed information pertaining to a matching STACK sequence. Alternatively, all clustered data for a specific STACK tissue can be accessed via WebProbe (**http://www.sanbi.ac.za/stackpack/webprobe.html**). A query from this page returns a summary report with links to detailed information for all clusters and linked clusters contained within a specific tissue category. For example, Figure 3(a) illustrates a query using an EST accession number (e.g., H64402). The

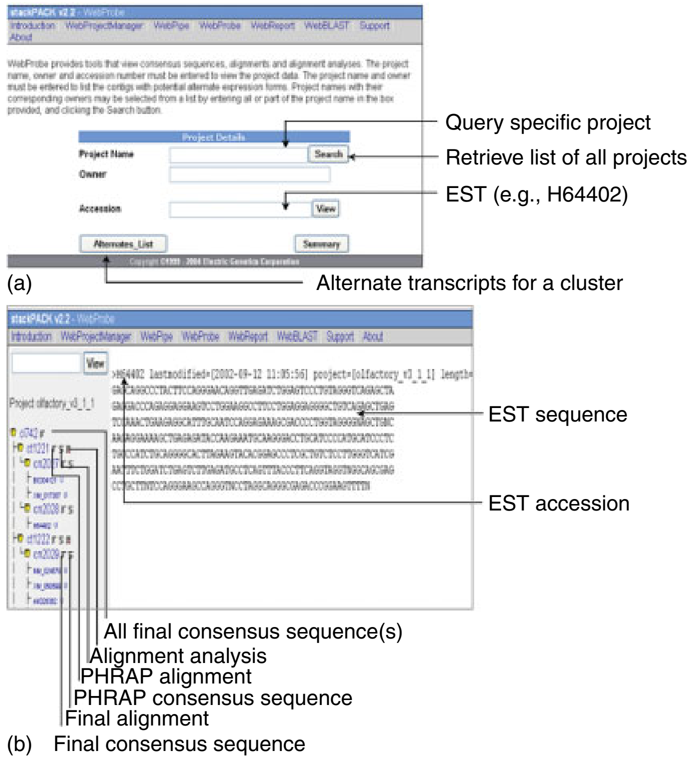

Figure 3 WebProbe, the STACK database extraction and viewing tool. (a) An EST is used as input to retrieve all clustered information relating to the specified EST identifier (H64402). (b) The corresponding cluster (cl742) is presented in a tree format with its contigs (ct1221 and ct1222). Consensus sequences cn2027 and 2028 corresponding to ct1221 and cn2029 corresponding to ct 1221 are displayed with constituent ESTs/mRNAs branching off from it

retrieved data are presented in two panels, namely, the right panel displays the EST sequence in FASTA format and the panel on the left displays the corresponding cluster in a tree format (Figure 3b) with its constituent EST accession numbers and hyperlinks to additional information such as PHRAP alignments, PHRAP consensus sequences, assembly analysis data, and final consensus sequences. Each EST identifier in the left panel has a UniGene hyperlink to search for corresponding UniGene records. Detailed documentation on each of the stackPACK^{TM} tools is available at **http://www.sanbi.ac.za/stackpack/webprobe.html.**

4. TIGR gene indices

The TIGR gene indices represent a collection of species-specific transcript databases. EST data and gene sequences are clustered and assembled into representative gene sequences or tentative consensus (TC) sequences using an alignment-based approach (Figure 1). The TC sequences provide putative genes with functional

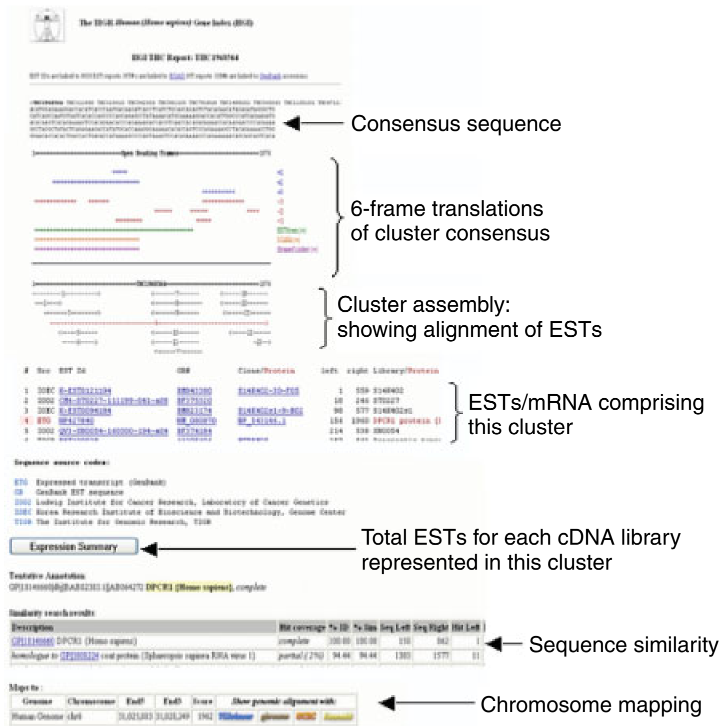

Figure 4 TIGR gene index report for THC1968564. The retrieved record contains a FASTA formatted contig sequence, followed by a 6-frame translation, assembly, constituent EST/mRNAs, relative level of expression, and sequence annotation. The assembly information has been reduced

annotation, a link to mapping data, and provide links between orthologous and paralogous genes through the TIGR Orthologous Groups Alignment (TOGA) database (see Figure 4; Quakenbush *et al*., 2001).

Sequence searches against TIGR gene indices are carried out with WUBLAST (**http://tigrblast.tigr.org/tgi/**). The BLAST results are hyperlinked to matching TC reports containing additional information in the context of the specific assembled transcripts (Figure 4). Alternatively, TIGR gene indices can be searched using a TC number that represents the most current version of a particular assembly, or an EST accession number. Integration of radiation hybrid mapping data allows the user to search for TC sequences that map to a specific genomic location.

5. Availability of UniGene, STACK, and TIGR gene index

UniGene cluster sequences, updated weekly, may be downloaded from the NCBI FTP site. The STACK clustering and visualization tools, stackPACK^{TM}, can be downloaded for different platforms from the SANBI FTP site. TIGR's clustering tools (TIGRCL), available for multiple platforms, can be downloaded from the

TIGR website. The TIGR gene indices are available for download as species-specific datasets.

Introductory Review

Microarrays: an overview

Jörg D. Hoheisel
Deutsches Krebsforschungszentrum, Heidelberg, Germany

1. Introduction

In recent years, DNA microarrays have become a synonym for genome-wide functional analyses. The power of the technology as an experimental tool derives from the specificity and relatively strong affinity of duplex formation of complementary sequences paired with the accessibility to analysis of very many fragments in parallel. In terms of molecular biology, DNA microarrays are an old technology already. This is documented by the widespread use of at least some microarray-based applications in laboratories across the world. At the same time, however, it is still an exciting and quickly developing field, since the full potential of assay formats that can be performed is currently not even conclusively defined let alone met. Also, accuracy, sensitivity, and speed of analysis are frequently not yet adequate and have large margins for improvement. As a result, the availability of arrays for routine testing is just starting.

2. The past

To some, it might look as if DNA chips appeared rather suddenly. However, as ever so often in research, it was a technology in the waiting. Gillespie and Spiegelman (1965) observed that single-stranded DNA binds strongly to nitrocellulose membranes in a way that prevents the strands from reassociating with each other but permits hybridization to complementary RNA. Development of a blotting technique by Southern (1975) proved to be a milestone in assaying nucleic acids. The technique, in all its modifications, was essential for many kinds of analyses, such as the identification of disease genes, and crucial for many achievements in the area of genomic research. Clone-filter arrays were introduced by Hans Lehrach (Poustka *et al*., 1986), permitting a reverse analysis format. The resulting parallelism in data production was a crucial step toward genome-wide analyses. The technique was initially designed for mapping purposes (e.g., Hoheisel *et al*., 1993) but quickly stretched out toward other applications (Lennon and Lehrach, 1991).

DNA microarrays on glass surfaces (Figure 1) made their debut then in the late 80s of the last century. Their parallel and independent conception by several groups (Bains and Smith, 1988; Khrapko *et al*., 1989; Drmanac *et al*., 1989; Southern

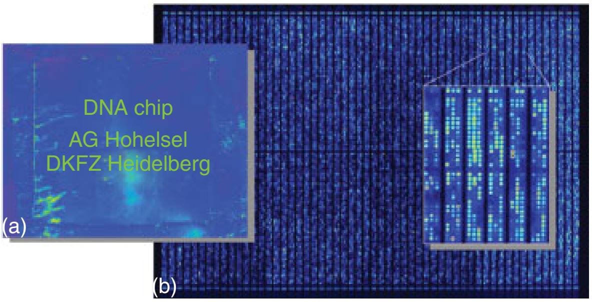

Figure 1 Six years difference: a small step in scale but a large step in complexity. Oligonucleotides were synthesized in situ, controlled by a lithographic mask that resembled some letters (a) or a micromirror system (b), respectively, and hybridized with a labeled DNA sample. While one oligonucleotide was synthesized in the former system, about 40 000 different ones are present on the latter chip, and more complex patterns are possible

et al., 1992) documents the fact that the time was right. Initially, the aim was the development of a tool that would permit the sequencing of the human genome, which at the time was thought to be achievable only with entirely new techniques. While proven wrong for the first (few) human genome(s), the methodology still is a promising contender for routine comparative sequencing. The development of means for the in situ synthesis of oligonucleotide arrays (Fodor *et al*., 1991; Maskos and Southern, 1992) made a relatively cheap and eventually reproducible production possible and made complex microarrays of many features more readily available. A first meeting on the technology was organized at the Engelhardt Institute in Moscow in 1991 (Cantor *et al*., 1992), assembling basically all scientists who were active in this field at the time, an accomplishment never to be repeated.

In terms of impact, the publication of Patrik Brown and colleagues on a preliminary transcriptional analysis of 27 *Arabidopsis* genes (Schena *et al*., 1995) was instrumental in attracting the attention of the wider research community. They did their analysis by a clever combination of techniques – basically all of which had been utilized previously but not in such combination – attaching cDNA PCR products to microscopic slides and using dual fluorescence coloring for detection. Apart from reporting on how such microarrays could be produced and analyzed in a format that biologists were used to, their main achievement really was the provision of a new perspective on what could be achieved by this technology.

3. The present

On this basis, DNA microarrays have become a tool that is commonly used for research purposes in both academia and commerce. Transcriptional profiling is currently the most frequently performed assay on DNA microarrays and starts to yield data, which not only improve the basic knowledge on biological processes but also support diagnosis and prognosis (e.g., Golub *et al*., 1999). Concomitantly, the data analysis tools – an integral and essential part of the analysis – are developing fast. While naturally starting out from many different approaches and protocols,

standardization begins to occur (MIAME; Brazma *et al*., 2001), although still at an insufficient level. Especially, the preparative steps that are prior to the actual chip analysis require much more rigorous standardization and more accurate recording. But even at the level of basic, relatively simple processes, such as normalization, different algorithms often result in a distinct data interpretation. A recent review on transcriptional studies on pancreatic tumors (Brandt *et al*., 2004), for example, demonstrated the inconsistency of such analyses. Of 978 genes that were found to be differentially transcribed in the 10 studies published to date, only 148 were identified in at least two studies, and not a single gene was identified in all studies. Worse even, frequently, there is a huge discrepancy between the genes prioritized by microarray studies and those identified by other means (Miklos and Maleszka, 2004). Much more care is needed in the experimental design, record taking, the actual analysis, and data evaluation to end up with reproducible results.

At the same time, new assay formats emerge, such as studies on epigenetic variations, RNA splicing, protein–DNA interactions, the selection of antisense or RNAi molecules, and such alike. It is apparent that not one microarray format alone will be optimal for all possible applications. Initially, microarrays were mostly made of oligomers, but PCR products or clone fragments took over relatively quickly, before oligonucleotides, short and long ones, became more dominant again. However, for analyses of protein–DNA interactions, for example, the use of DNA fragments is favorable, since most if not all of a genome could be covered that way. Therefore, it seems likely that several chip formats will coexist for a foreseeable future, although in situ synthesis and thus oligomer microarrays are superior with respect to achieving high and verifiable quality.

Currently, microarray technology is beginning to divide into two distinct areas, routine assays on the one hand and research studies on the other. The former type of analysis will eventually require microarrays of low complexity but produced in really large numbers. Research also moves away from the very complex arrays of global coverage, which will mainly be used for initial screens only. At the same time, the need for flexible design and production processes is increasing substantially, which is not surprising given the increase in the number of users, assays, targets, and applications as well as the need of combining all these for a more comprehensive picture. Coincidentally – or maybe not – several large companies that are related to electronic chips rather than biology are investing in the field of biological microarrays. Apart from the financial and commercial aspects, they bring in the much needed expertise and experience in matters such as stringent quality control and marketing, which are essential ingredients of making microarrays a success in the diagnostics market.

4. The future

Apart from the diversification and partition of the field of DNA microarrays, the technology is advancing still with respect to technology. Miniaturization not only of the chips themselves but even more importantly of their environment is actively pursued. Simultaneously, since dependent on the above, signal detection down to individual molecule interactions is another focus of development. And concurrent to

this, the quantification of the absolute signal intensities is important, too. Toward routine application, efforts are ongoing to simplify the usually rather complex process of sample preparation. Various methods exist for avoiding both initial amplification and labeling of the sample material prior to analysis. In conjunction with this, alternative modes of measurement are developed. This includes the identification of mass changes on cantilevers (Arntz *et al*., 2003), for example, the detection by mass spectrometry of phosphates of nucleic acids that hybridize to catching molecules made of phosphate-free DNA-mimics (Brandt *et al*., 2003) or a direct electronic detection by means of conductance or impedance measurements (e.g., Hahm and Lieber, 2003).

On the basis of the experience gathered at the level of nucleic acids, also other molecule classes become more and more the focus of developments for analyses that are similar in type, scale, and complexity to what is achieved on DNA chips. As a matter of course, much is still to be learnt before such experiments are performed at a level achieved with nucleic acids today. Even more difficult will be the interpretation of the resulting data or their translation into information that is useful for diagnostic purposes. However, developments are rapid and the demand for such assays is increasing. This kind of information is needed for the ability to describe a (simple) biological model in silico. Termed "systems biology", such an approach is hampered by the lack of data, since only then the appropriate algorithms can be developed and evaluated and eventually the complex and dynamic interactions in biological systems be described.

Creating and hybridizing spotted DNA arrays

Ivana V. Yang
Duke University Medical Center, Durham, NC, USA

1. Introduction

The ability to study transcription of all genes in an organism in parallel using gene-expression profiling has revolutionized both basic and clinical science fields (Ramaswamy and Golub, 2002; Staudt and Brown, 2000). Over the past decade, microarrays have evolved from a specialized and expensive tool used in small numbers in a few laboratories to an almost standard technique available and affordable to many researchers. Although not fully mature, both microarray technology and data analysis protocols have been refined to the point that high-quality data can be obtained relatively easily and quickly. This review focuses on recent advancements in printing and hybridizing spotted DNA arrays, and discusses some general aspects of experimental design and data analysis for two-color hybridization assays.

2. What to print?

The first step in creating spotted DNA microarrays is the choice of the DNA material to print. DNA fragments generated by the polymerase chain reaction (PCR) amplification from bacterial cDNA clone sets were the original source of the printing material (Schena *et al*., 1996) and are still used by a number of established microarray laboratories. Sequence-verified cDNA clone sets for many organisms, including mouse, rat, and human, have been made available to researchers through public efforts (Table 1a) (Lennon *et al*., 1996). Analysis and clustering of expressed sequence tags (ESTs) to identify underlying genes (Boguski and Schuler, 1995; Quackenbush *et al*., 2000) provides annotation for cDNA clones and typically includes information such as identifiers from multiple databases, gene ontology (GO) functional categories, chromosome locations, and the presence of orthologs (*see* Article 80, **EST resources, clone sets, and databases**, Volume 4).

An alternative PCR strategy is employed for microarray studies of organisms with smaller and simpler genomes (bacteria, parasites, yeast) (DeRisi *et al*., 1997) and for organisms that are not well represented in publicly available clone

collections (Kim *et al*., 2003). In these cases, DNA fragments are prepared by PCR amplification from genomic DNA using gene-specific primer sets; the challenge in this approach lies in effective primer design to ensure efficient high-throughput PCR amplification.

A major shift toward printing long, unmodified oligonucleotide probes (generally 70-mers) instead of PCR products has emerged in the past couple of years owing to both an increase in the availability of genomic sequence and the decrease in the cost of oligonucleotide synthesis. Oligonucleotide libraries are an attractive alternative not only because clone sets and PCR reactions are eliminated but also because they provide more versatility in the types of projects that are possible to conduct using microarrays. For example, alternative splicing can be examined by designing probes for multiple exons within a given gene (Clark *et al*., 2002; Johnson *et al*., 2003); it is estimated that as many as 50% of human genes have splice variants and many of these may be relevant to human disease.

Melting-temperature matched libraries of 70-mers with high specificities for target genes are commercially available (Table 1a) or can be designed by individual investigators using software packages designed for this specific purpose (Rouillard *et al*., 2003; Wang and Seed, 2003). Direct comparison studies of spotted oligonucleotide and PCR product microarrays have shown that the two types of probes provide comparable sensitivity and specificity, and that there is an excellent correlation between expression ratios obtained using the two approaches (Wang *et al*., 2003; Woo *et al*., 2004).

3. Array printing

The most popular printing substrates are aminosilane-coated slides because they require no modifications in the DNA molecules for the efficient immobilization on the slide surface. Positively charged primary amine groups form ionic bonds with negative charges on the DNA phosphate backbone, and this electrostatic interaction is enhanced by DNA cross-linking to the slide surface using ultraviolet light and/or heat. Alternative attachment strategies include in-house coated poly-L-lysine slides and commercially available aldehyde and epoxide substrates (Table 1b). In addition to the amount of DNA immobilized on the slide surface, important criteria in evaluating printing substrates are spot morphology and background signal (see Section 5).

Spotted arrays are created by printing very small volumes of DNA material onto precise locations on glass substrates using robots (Table 1c) equipped with spotting pins. The choice of printing buffer, PCR purification protocol, temperature, and humidity are crucial to obtaining high-quality arrays (Hegde *et al*., 2000). Improvements in spotting pin technology, robot precision, and substrate chemistries have allowed investigators to print large quantities of high-density arrays (up to 60 000 elements) in as little as a few days.

4. Target preparation and hybridization assays

Labeled targets for two-color hybridization assays have typically been generated by incorporation of fluorescently labeled deoxynucleotide triphosphate (dNTP) analogs into reverse transcribed cDNA, but this direct incorporation strategy suffers from low incorporation efficiencies and dye bias due to the bulky nature of cyanine 3

(Cy3) and cyanine 5 (Cy5) dyes. In indirect or aminoallyl labeling, 5-aminoallyl-dUTP is incorporated into cDNA during reverse transcription (RT), and this is followed by a chemical coupling reaction of Cy dye esters to the aminoallyl linker. The third approach, dendrimer labeling, differs from both direct and indirect incorporation methods in that it is not dependent on modified dNTP incorporation but rather relies entirely on hybridization kinetics. Both aminoallyl and dendrimer labeling protocols offer the advantages of improved incorporation efficiencies and reduced dye bias as compared to direct incorporation (Manduchi *et al*., 2002).

To facilitate studies of small numbers or even single cells in applications such as fine needle aspirate biopsies, laser-capture microdissected, or flow sorted cells, RNA amplification protocols have been developed and optimized for microarray purposes by a number of laboratories and commercial entities (Table 1d). These protocols are based on the T7-linear amplification method first described by Eberwine (Van Gelder *et al*., 1990). The main concern in hybridizing amplified products is that the original transcript representation may be distorted during the amplification process. Several studies have shown that transcript representation is preserved during amplification, thus validating the use of RNA amplification schemes in microarray analysis (Iscove *et al*., 2002; Zhao *et al*., 2002). The amplification strategy has facilitated the first microarray profiling of human blood samples (Whitney *et al*., 2003), an important step toward bringing gene-expression profiling into the clinic.

Cy3- and Cy-5-labeled samples are cohybridized to the immobilized PCR products or oligonucleotides in a competitive hybridization assay. Following a prehybridization step to block nonspecific binding to the positively charged substrate surface surrounding the DNA spots (Hegde *et al*., 2000), labeled targets are incubated on the slide overnight. After a series of washing steps to remove unbound targets, arrays are scanned using instruments equipped with scanning confocal lasers, and image analysis and feature extraction are performed using either software provided with the scanner or other software packages (Table 1e).

5. Quality control

Quality control measures have been implemented in most laboratories for both array production and hybridization assays. Several slides from each printing batch are usually stained with an intercalating fluorescent dye that is detected either in the green or in the red channel (Wang *et al*., 2003). Screening the slides in this way allows for the detection of problems that may have occurred during the printing run, such as a hung up pin or a change in humidity or temperature. Spot morphology is also indicative of substrate quality and any defects in the slide surface are also diagnosed using this DNA staining technique.

Most laboratories have also adopted a practice of printing positive and negative controls in multiple positions on each slide. Negative controls are important for assessing the level of nonspecific hybridization and include spotting buffer, polyA DNA, salmon sperm DNA, and random oligonucleotide sequences. Positive or spike-in controls are genes from a different species that do not have sequence homology to the species of interest (e.g., *Arabidopsis thaliana* for mammalian

arrays). cRNA for these genes is spiked into the labeling reactions at different relative copy numbers, and any deviations from expected ratios are indicative of problems in hybridization conditions (Wang *et al*., 2003). Printing controls at multiple positions on each slide allows for detection of any spatial gradients and artifacts. Finally, a number of quality control metrics for the image processing step have been proposed (Brown *et al*., 2001; Wang *et al*., 2001), and almost all image analysis software packages have incorporated some type of quality control measure.

6. Experimental design

One of the biggest challenges in applying microarray technology is the question of experimental design. Investigators need answers to questions such as which samples should be cohybridized, how much replication is necessary, robustness of design, dye bias, sample size, and statistical power needed to ensure that the experimental objectives are achieved. Although much has been learned over the years through trial and error and statisticians have provided recommendations based on mathematical models (Churchill, 2002; Dobbin *et al*., 2003; Yang and Speed, 2002), there is still no simple answer for how a given experiment should be designed. Experimental design will depend heavily on the type of study and the amount of funding available for microarray analysis.

In the simplest design, a query sample (treated in some way) is compared to the reference (untreated) sample on a single array. However, most projects require comparisons of many samples across many arrays, and this type of analysis is facilitated by the use of a common reference. Each sample of interest is cohybridized with the reference sample, which can be either a pool of all samples included in the project or an unrelated "universal" reference sample. Universal RNA reference pools are constructed from a large number (10 or more) of cell lines or tissues and are commercially available (Table 1f). The idea underlying such a design is that by combining RNAs from diverse cell lines, one might obtain a more complete representation of the genes spotted on the array. An alternative to the common reference design is "loop" design, in which each experimental sample is hybridized with two other experimental samples to form a loop (Churchill, 2002). The advantage of the loop design is that more data are collected on samples of interest instead of an irrelevant reference sample. The disadvantage is that information is lost for many genes when samples that are further apart in the loop are compared. Furthermore, data coming out of loop designs are more complex, thus requiring specialized analysis tools.

In addition to careful experimental design, incorporating replicate experiments allows researchers to deal with the unwanted sources of variation in their microarray experiments. Spotting the same DNA on each slide multiple times is one type of replication, but within-arrays replicas have generally shown good correlations and thus have often been eliminated to make room on the array for additional sequences that provide better genome coverage. Hybridization assay replicas include both technical replicates, in which the same RNA sample is labeled and hybridized multiple times, and biological replicas, in which RNA samples from multiple cell

line growths or individuals are used. A special type of technical replication is dye flip assays; in this case Cy3 and Cy5 labels are reversed to eliminate any dye bias. The most commonly asked question in experimental design is how much replication is necessary. Several recommendations have been made recently based on statistical models derived from the body of data available to date (Dobbin *et al*., 2003; Pavlidis *et al*., 2003; *see also* Article 52, **Experimental design**, Volume 7).

7. Data analysis

After data have been collected and images processed, the first step in the analysis of two-color array data is to normalize the relative fluorescence intensities in Cy3 and Cy5 channels. Normalization and data transformation are dealt with elsewhere in this encyclopedia and are only discussed briefly in this chapter. Normalization adjusts for experimental variation such as differences in labeling and detection efficiencies for the fluorescent dyes and for differences in the quantity of input RNA from the two samples examined in the assay. A number of global normalization approaches have been described (Quackenbush, 2002); however, none of these methods take into account systematic, intensity-specific biases that are often seen in the data. Locally weighted linear regression (lowess) (Cleveland and Devlin, 1988) analysis has been shown to successfully remove intensity-specific effects in Cy5/Cy3 ratios (Yang *et al*., 2002b), and lowess normalization has since become the most widely used approach for balancing the two channels. This method can be applied to either the entire array or subsets of elements based on the position to eliminate any spatial effects that may appear in the data. Once data have been normalized, we can begin to make meaningful comparisons of expression levels across many experimental conditions.

Microarray analysis is used to ultimately answer the question of which genes are differentially regulated between control and test groups. Deciding what the cutoff value used to distinguish differential expression from natural variability in the data is a challenging task. A cutoff of twofold up- or down-regulation was chosen to define differential expression in early microarray studies (Schena *et al*., 1996). However, using a single cutoff value may not be appropriate since background noise is much greater, relative to signal, at lower fluorescence intensities. Several groups have therefore proposed and tested methods for intensity-dependent estimation of differential expression (Baggerly *et al*., 2001; Ideker *et al*., 2000; Yang *et al*., 2002a). Statistical testing has also become a widely used approach to defining differential expression across many experiments. Both existing statistical methods, such as analysis of variance (ANOVA) (Cui and Churchill, 2003), and algorithms developed specifically for microarray data (significance analysis of microarrays or SAM) (Tusher *et al*., 2001) have been successfully applied in microarray data analysis. Detailed description of application of statistical methods to gene-expression analysis can be found in Article 53, **Statistical methods for gene expression analysis**, Volume 7 and Article 59, **A comparison of existing tools for ontological analysis of gene expression data**, Volume 7. Subset(s) of genes that pass the test, that is, are significantly differentially expressed between experimental

groups, can then be used for further analysis and data mining (Quackenbush, 2001; Slonim, 2002).

8. Validation

It has become a common practice to validate relative expression levels of a small number of genes identified as differentially regulated in a microarray experiment by either more traditional techniques such as semiquantitative RT-PCR, ribonucleotide protection assay (RPA), and Northern blot analysis, or by recently developed real-time quantitative RT-PCR assays (Chuaqui *et al.*, 2002). The conclusion drawn from a large number of studies to date is that expression ratios obtained from microarrays and single-gene techniques are in agreement in terms of the direction of change (up- or downregulated) but frequently differ in detected fold changes. Investigators often choose the genes with the highest differential expression ratios for further study, but this strategy may overlook potentially interesting genes that have small fold changes in a microarray experiment but could be more differentially expressed when studied using other approaches. A better alternative for selecting genes to be validated is based on their function and relevance to the biological process that the investigator is addressing in the study.

9. Conclusions

Since their conception 10 years ago, spotted microarrays have evolved into a tool that produces reliable gene-expression data at the whole-genome level. Availability of genomic sequence combined with improvements in substrate chemistries and spotting technologies have led to the ability to print probes for entire genomes at least once on a single slide. Advances in protocols for RNA amplification and target labeling allow researchers to obtain high-quality data from samples with limited amounts of RNA. Finally, sophisticated algorithms for normalization, integration of replicate experiments, and identification of differentially expressed genes have been developed to deal effectively with undesirable technical variability in microarray data. The challenge in the field of spotted microarrays now lies primarily in data mining and integration of gene-expression profiles, with findings from other "-omic" sciences into a system-level understanding of biological systems.

Using oligonucleotide arrays

Lindsay W. Mitchell and Eric P. Hoffman
Children's National Medical Center, Washington DC, USA

1. Introduction

Manufacture of nucleic acid microarrays typically involves the placement of purified DNA fragments onto specific "addresses", or locations, of an underlying solid support. The DNA fragments can be double-stranded PCR products, cloned plasmids, or shorter single-stranded oligonucleotides (25–70-mers). In each case, every specific purified DNA on the solid support comprises a "feature" of the array and an array may contain thousands or millions of different features, each having an independent specific address on the microarray. Complex solutions of mRNAs from cells or tissues are labeled (typically directly or indirectly labeled with fluorescent dyes) to enable detection by laser scanning. Labeled solutions are then placed onto the microarray, and hybridization between the solution-based probe and immobilized target-sequence on the microarray occurs. Laser scanning is then used to quantify the amount of labeled mRNA on each feature, and normalization of resulting signals allows derivation of a relative concentration of each mRNA in the original solution. Sensitivity and specificity of microarray assays depend on many factors including the length of the target sequence, GC content, and consistency and efficiency of mRNA labeling. This review focuses on Affymetrix arrays, a particular, but commonly used microarray platform for mRNA profiling (see **http://www.affymetrix.com**).

Other important applications of microarrays include analysis of genomic DNA. Linkage analysis of disease traits within families can be accomplished using microarrays that detect polymorphisms throughout the human genome. In this application, 25-mer oligonucleotides are designed to detect single nucleotide polymorphisms (SNPs) by differential hybridization of the genomic DNA probe to the allele-specific target sequences. The ratio of hybridization signals to features querying each of the two alleles of an SNP (e.g., either G or T polymorphism) determines the genotype of that subject's DNA. Current Affymetrix arrays for detecting polymorphisms query 100 000 distinct positions in the genome (loci) using a two microarray set, providing coverage of the genome with a polymorphism roughly every 30 000 bp (*see* Article 77, **Genotyping technology: the present and the future**, Volume 4). Comparative genomic hybridization (CGH) queries the relative amount of each of the 100 000 loci (independent of the genotype at the polymorphic site), so these same "SNP chips" can be used to scan for deletion or amplification of regions of the genome in patient tumors as well (*see* Article 93, **Microarray CGH**, Volume 4).

All microarrays work on the same principle of hybridization of a complex solution of labeled nucleic acids (mRNA or genomic DNA), to specific sequences placed in specific addresses on a solid support (the array). For this reason, the data obtained by the 25-mer in situ synthesized Affymetrix arrays is, in principle, similar to the data obtained by mechanically spotted cDNA microarrays (PCR products), or mechanically spotted arrays of longer, machine-synthesized oligonucleotides (e.g., 70-mers; see **www.appliedbiosystems.com**). In practice, however, there are some clear distinctions between these experimental platforms that serve to make the data obtained quite distinct. First, mechanically spotted arrays of oligonucleotides and PCR products (cDNA arrays) typically suffer from greater variation in the amount of nucleic acid spotted and retained on the surface of the solid support than do in situ synthesized arrays. Thus, it is important to have methods of normalizing the resulting hybridization signals to the amount of target in the feature, and this is typically executed by cohybridizing a "control" RNA sample labeled with a different color fluorescent molecule followed by derivation of a ratio of hybridization signals (experimental/control) for each feature. In contrast, Affymetrix arrays are chemically synthesized in situ using photolithography, resulting in very consistent array-to-array amounts of target nucleic acid at each feature. Thus, RNA samples can be hybridized individually (no cohybridization) and signals are normalized across the entire array or across all arrays within a project. Generally, there are fewer technical sources of variation with Affymetrix arrays than with mechanically spotted arrays. It should be noted that there are other in situ synthesized microarrays, most notably from Agilent, whose arrays contain a single 60-mer probe for each gene; these arrays are generally used in two-color assays.

A second major distinction between platform types concerns the number of measurements taken per transcript, sometimes referred to as "redundancy" or repeated measurements. Spotted oligonucleotide or cDNA arrays typically use one feature per transcript measured. Thus, the resulting signal is generated from a single fluorescent measurement. Affymetrix arrays use "probe sets", which contain multiple perfect match (PM) and mismatch (MM) oligonucleotide features (targets) querying each transcript. Current arrays use 11 perfect match and 11 paired mismatch (a single substitution relative to the reference in the center – 13th position – of the oligonucleotide) for each probe set (Figure 1). As a result, there are 11 relatively independent measurements that are used to derive a single "signal" for a corresponding mRNA as well as 11 estimates of the corresponding background. This repeated measurement provides better control over technical variation (feature-to-feature variability), and variations in performance (hybridization efficiency, etc.) of different features detecting a specific mRNA. The interpretation of probe set–generated data (probe set algorithms) has become an active area of research, as covered in more detail below. The third distinction between platform types is the relative ease of providing quality control, standard operating procedures, and database resources for standardized, factory-manufactured platforms such as Affymetrix microarrays (see Tumor Analysis Best Practices Working Group, 2004). While spotted oligonucleotide and cDNA microarrays are much more flexible in their content, this same asset becomes a liability when attempting to standardize data reporting and interpretation between

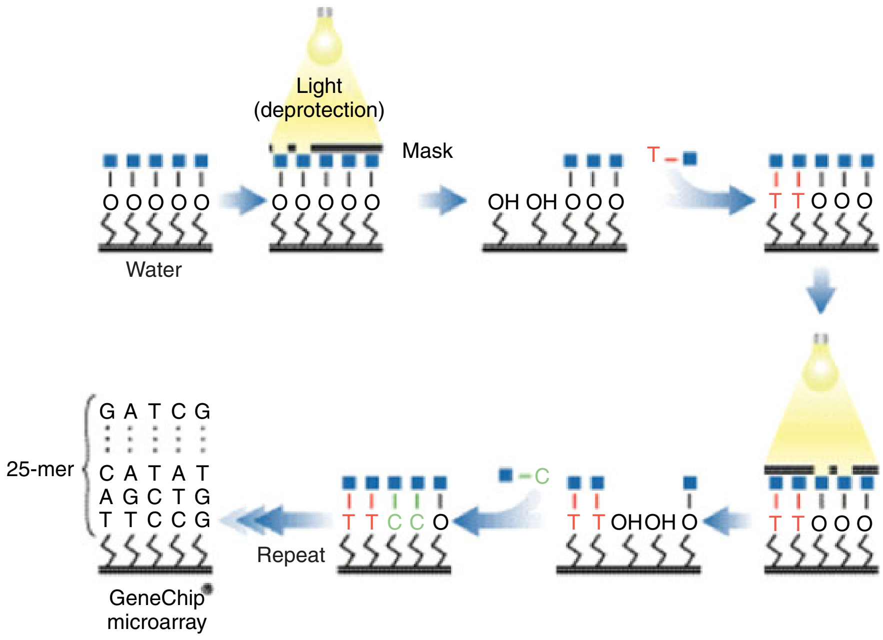

Figure 1 Photolithographic masks are strategically placed so that only features requiring the nucleotide being added are deprotected and made ready for nucleotide binding. (Reproduced by permission of Affymetrix, Inc.)

different laboratories (*see* Article 91, **Creating and hybridizing spotted DNA arrays**, Volume 4).

In what follows, we focus on Affymetrix arrays, describing microarray manufacture, use, and data interpretation.

2. Production of Affymetrix arrays

Manufacture of Affymetrix microarrays begins with a piece of quartz. A washing process serves to render natural surface hydroxylation uniform so the quartz can then be bathed in silane that reacts with the hydroxyl groups to create a network of covalently linked molecules. This network serves as the platform for the synthesis of anchored oligonucleotides. The distance between covalently linked silane molecules is the limiting factor in determining what synthesis density is possible on the array. (Current Affymetrix microarrays contain over 1 million features in a 1.2 cm^2 solid support, and this density is increasing rapidly.) Photoresponsive linker molecules are then attached to the silane and photolithographic masks are strategically placed over the surface of the quartz with gaps in all locations where growing oligonucleotides require addition of whichever nucleotide base is to be included in the next wash. For each step of nucleotide addition, masks are placed in different locations to allow different oligos to be synthesized in parallel. UV light above the mask passes through holes in the mask to activate discrete regions on the surface (Figure 1) by deprotecting linker molecules, making them receptive to nucleotide

coupling. Once the placement of masks, UV excitation, and nucleotide wash is repeated a sufficient number of times to generate the desired ~25-mer probes at each feature, the quartz is placed in flow cell cartridges for ease of use in the hybridization and staining wash steps. Each batch of arrays synthesized in this manner is subject to hybridization with control cocktails to assess the quality of the manufacture process.

The selection of the 25-mer sequence to be synthesized at each array address is a critical part of microarray design. Each 25-mer is only a small fraction of the complete mRNA being queried, thus, the selection of the best set of well-matched sensitive and specific probes is important for the accurate measure of transcript abundance. To make this decision, Affymetrix compiles sequence and annotation details from databases such as GenBank, RefSeq, and dbEST (see **http://www.ncbi.nih.gov**) and uses information therein to group transcripts into similar clusters. These clusters are aligned to the human genome to identify which transcripts are splicing and polyadenylation variants of one another. On the basis of this information, Affymetrix either chooses one representative "exemplar" transcript to use in probe set design for a given gene or selects a series of consensus sequences in cases when a superior representative transcript choice is not available. The 3′ and 5′ orientation of the exemplar and consensus sequences is then determined, and in cases in which this cannot be unequivocally established, probe sets are designed for both strand orientations. Of all the possible 25-mer probes that could query an exemplar or consensus sequence, a few are selected that best fit several criteria. First, the probes must have minimal possible chance of cross-hybridization with other, unrelated transcripts. Second, probe sets are selected that are located at the 3′ end of the transcript for compatibility with the poly-A-based target preparation (amplification) process described in the next section. Finally, probe sets are evaluated for anticipated hybridization efficiency under the given pH, salt, and temperature conditions used in assays.

Similar hybridization microarrays are used for purposes other than mRNA profiling. Affymetrix microarrays are available that detect DNA polymorphisms (single-nucleotide polymorphism genotyping, or "SNP typing"), or provide DNA sequence from a patient (resequencing arrays). The microarrays that query DNA sequence are also produced in the manner outlined above and work by detecting the amount of hybridization from probes in solution to target sequences on the quartz surface. The major distinction is that relative hybridization to different sequences at a single base position are detected. For example, to genotype or sequence DNA segment X, four 25-mer features are synthesized with sequence variation only in the center of the oligo: . . . ATA . . . ; . . . AGA . . . ; . . . ACA . . . ; . . . AAA . . . If the probe hybridizes best to the . . . AGA . . . feature, this indicates that the correct DNA sequence in that patient contains Guanine in the position being queried.

3. Target preparation and hybridization for mRNA profiling

Preparation of target samples for use with a gene expression array first involves the isolation of total RNA from the cells or tissue of interest. This entails homogenizing

the tissue or lysing the cells in combination with chaotropic agents to disperse the tissue and prevent RNA degradation. RNA is then extracted from this lysate using phase separation with chloroform followed by cleanup to remove DNA and protein contamination. Following isolation, RNA is quantified by spectrophotometer UV absorption at 260 wavelength. Quality is assessed by determining the integrity of the 18s and 28s ribosomal RNA bands by gel electrophoresis or other similar approaches.

The total RNA is then used as starting material for amplification and labeling prior to hybridization to the microarrays. Labeling is executed to enable detection of the bound probe on the microarray feature after hybridization. Amplification is necessary to increase the amount of mRNA present in isolated total RNA to a quantity sufficient for effective hybridization and detection (at least 400 times the starting amount). Depending on the amount of RNA isolated, one (~1–15 μg starting material) or two (~10–100 ng of starting material) rounds of amplification are required. While the principles in play are identical for both one- and two-round amplification protocols, maintenance of transcript integrity is generally poorer in samples processed through two rounds, making more lenient QC necessary and complicating the comparison of data generated by one- and two-round protocols.

In both cases, the first step of amplification is the generation of complementary DNA from polyadenylated transcripts, which correspond to protein-coding sequences (mRNA), as distinguished from transfer RNA (tRNA), ribosomal RNA (rRNA), and other RNA species (hnRNA). This is accomplished through the use of an oligo(dT) primer that binds to the mRNA poly-A tail and primes reverse transcription into a DNA/RNA hybrid molecule using reverse transcriptase (Figure 2). DNA polymerase I and random primers in combination with RNase H are then used to replace the RNA strand with DNA, leading to the synthesis of double-stranded cDNA. The amplification step follows, with the cDNA serving as a template for T7 RNA polymerase, leading to production of 400 or more RNA molecules from each cDNA molecule (Figure 2). Biotinylated nucleotide precursors are included in the reaction, so that the resulting copy RNA (cRNA) is internally labeled with biotin (Figure 2). If the first round of cRNA production does not lead to adequate amounts of probe, then the process can be repeated (cRNA to cDNA to second round cRNA). All amplification procedures introduce some bias, however, as some transcripts amplify better than others. Thus, it is essential to follow the same protocol for samples that will be compared as evidence suggests this bias is sequence specific.

Quantity and quality of amplified, labeled cRNA is determined before fragmentation (UV absorbtion at 260 and cRNA smear between 100–300 bp on an agarose gel). 15–20 μg of quality cRNA is fragmented by heating to produce ~50 bp segments. This size is optimal for interaction of target with probe and successful consistent hybridization. Because the targets themselves are only 25-mer in length and query a unique part of the entire transcript, maintenance of the entire transcript as a complete unit is unnecessary for measuring transcript abundance. Fragmented cRNA is checked again by gel electrophoresis to confirm size (~50 bp) and is then combined with reagents for array hybridization. Also included in the hybridization reagent mix is Oligo B2, a synthetic oligonucleotide that binds to probes located around the perimeter of the array and arranged in a checkerboard

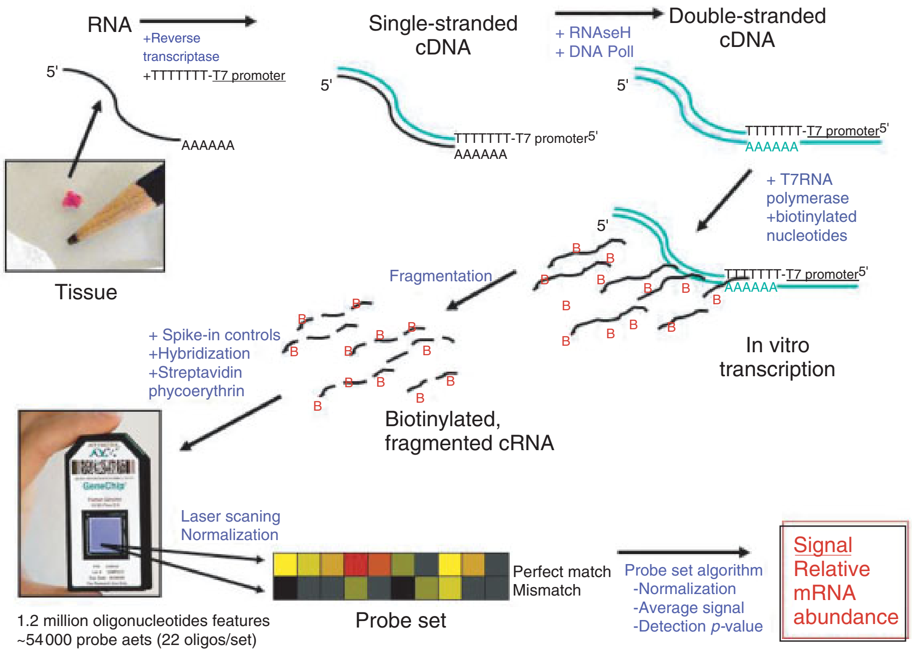

Figure 2 The steps used to process tissue or cells through RNA isolation, cDNA synthesis, cRNA amplification, labeling, hybridization, and image generation of affymetrix microarrays

pattern at each corner. These oligos assist in alignment of an interpretive software grid with fluorescent signal on the array.

Hybridization cocktails containing fragmented, biotin-labeled cRNA, spike-in controls, and buffers are introduced into the flowcell casing that encloses the array. The arrays are then incubated for 16 h at controlled temperature with mixing to allow the hybridization of the labeled probes in solution to the target feature on the microarray surface. After incubation, the hybridization cocktail is removed, the array washed, and the bound biotinylated probes are stained with streptavidin (biotin binding) complexed with the fluorescent molecule phycoerythrin. This streptavidin-phycoerythrin antibody complex (SAPE) provides a fluorescence-based "report" of how much transcript is bound to any given feature on the array. This fluorescent report can be amplified by subsequent staining with biotinylated goat anti-streptavidin antibody and then again with phycoerythryn-labeled streptavidin antibody. The amount of fluorescence on the array is assessed before and/or after amplification with a laser scanner also manufactured by Affymetrix (Figure 2).

4. Data analysis; brief overview: feature – probe set – microarray – project – interproject

The scanned image of a hybridized array is stored as a pixel-based image file (.DAT) and this image is processed to determine the amount of fluoresence signal

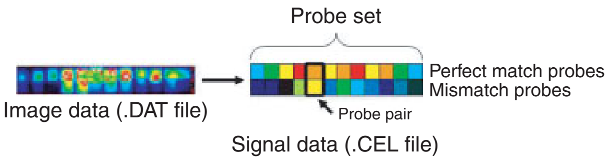

Figure 3 The anatomy of a probe set. Each mRNA transcript is queried by a series of oligonucleotides, with either perfect match or mismatch design against specific 25-bp regions of the transcript. Typically, 11 probe pairs (perfect match and mismatch partners) are used for each probe set. The resulting scanned image of a probe set is shown in the lower left panel, with the resulting normalization and averaging shown in the right panel pair. Signal data for each feature is stored in a .cel file, and probe set algorithms typically use this file to derive a single expression "signal" for each probe set

at each of the 1 million features (.CEL file) (Figure 3). This data is then processed to derive a single, numerical signal for each probe set. As discussed above, one of the advantages of the Affymetrix platform is the multiple measurements that are taken for each transcript; 11 probe pairs (composed of perfect match and mismatch partners) are designed against distinct parts of the mRNA to be queried (Figure 3). The mismatch probe contains a single substitution in the center position, which destabilizes specific hybridization, providing an estimate of nonspecific hybridization to the perfect match probe. Thus, the simplest measure of transcript abundance is to subtract the mismatch fluorescence signal from the perfect match for each of 11 probe *pairs* within a probe *set* and then average and normalize the signal for each probe set within the *microarray* (Figure 3). The normalized "signal" for each transcript (probe set) is then a single number that can be compared between microarrays within the same *project*, or between different projects (though consistent laboratory protocol is crucial for *interproject* comparison). In this flow of data interpretation, one progressively works from the feature – to probe pair – to probe set – to microarray – to project – to interproject analysis.

There are many approaches to both derivation of a single "signal" from a probe set, and also many methods of normalization of signals so that different microarrays can be accurately compared to each other. Methods for deriving signal are typically called "probe set algorithms", and these aim to extract the greatest amount of accurate information content from a probe set (sensitivity) while also reducing the amount of noise (specificity) (*see* Article 54, **Algorithms for gene expression analysis**, Volume 7). We have recently compared a number of probe set algorithms, and have found that different algorithms are optimal depending on the specific application. For example, a more "stringent" probe set algorithm may provide better data analysis in a "noisy" experiment where there are many uncontrolled confounding variables. On the other hand, an algorithm that ignores the mismatch signal can be much more sensitive in detecting low-level hybridization signals (Seo *et al*., 2004).

To briefly describe the logic of a particular probe set algorithm (MAS5.0 provided by Affymetrix), the first step in calculating expression value (probe set signal) is an estimation of background signal (fluoresence) present on the array. The array is divided into 16 regions and the lowest 2% of signals in that region are taken to represent background signal in that zone. The finalized background value takes into

account the background in all other zones (each weighted by its distance from the zone in question), in order to smoothen background estimations across the entire array. Probe signal intensities in each zone are then adjusted by subtraction of that zone's background from the intensity of each feature contained therein. A threshold is set to ensure that this subtraction does not result in any negative intensity values. These background-adjusted intensities can then be used to calculate gene expression values. As described above, the basic principle involves finding the difference in intensity between each PM and MM probe *pair* and averaging the differences of every probe pair in a given probe *set*. This results in a single "average difference" value for each probe set and represents a relative level of expression of the gene queried by that particular probe set.

In addition to providing this numerical representation of transcript behavior, the MAS5.0 software also provides an "absolute" call for each probe set. This metric results in every probe set being labeled as "Present", "Absent", or "Marginal" and serves as an indicator of the reliability of the numerical expression value assigned to the probe set. To assign an absolute call to a probe set, an absolute call is first assigned to each probe pair within that probe set. A probe pair is considered Present if its difference (PM-MM) is greater than or equal to a set threshold and if its ratio (PM/MM) is greater than or equal to a second set threshold. A probe pair is considered Absent when neither of these conditions is met (MM-PM and MM/PM are both greater than or equal to the set thresholds). The difference and ratio thresholds are established on the basis of calculated noise (defined as the variation in digitized signal of the laser scanner as it reads intensity from the array surface) and whether the array was stained once with phycoerythryn streptavidin or amplified by staining twice. On the basis of the absolute call of each probe *pair*, an overall absolute call for the probe *set* can be calculated. Three values are used in making this determination. The first value is the ratio of probe pairs called Present to those called Absent. The second value is the positive fraction, or the number of probe pairs called Present divided by the total number of probe pairs in the probe set. The third value, Log Average Ratio, which takes into consideration the numerical expression value, provides an estimation of the influence of cross hybridization. (The Log Average Ratio is calculated by averaging the log of PM/MM values of all the probe pairs in the probe set and multiplying by 10). These three parameters, Positive/Negative Ratio, Positive Fraction, and Log Average Ratio, are considered in the context of a scale with user defined thresholds below which a probe set is called Absent, above which a probe set is called Present, and between which a probe set is called Marginal. It has been demonstrated recently that cross-hybridization on arrays is largely dependent on the GC content of each particular probe. For this reason, a proposal for newer versions of Affymetrix arrays includes implementation of more general cross-hybridization assessment in place of the sequence-specific MisMatch probes that are currently employed. Each probe would then be compared to one of several general cross-hybridization controls that matched its particular GC content profile. This approach would free space on the array for additional target querying probes while still maintaining effective assessment of noise and probe specificity.

MAS5.0 software also includes array-wide normalization of expression values to a user-defined target intensity value. This normalization maintains all *relative*

relationships between probe sets/transcripts on an array but brings them within the user specified scale. This allows arrays normalized to the same target intensity to be more effectively compared to one another. The software reports the scaling factor that was used to adjust all intensity values on the array closer to the set target intensity, which allows the user to identify arrays within a project for which more extreme adjustment was necessary (indicating possible problems with target transcript integrity, hybridization etc.).

The standardized Affymetrix microarrays permit the development of robust probe set algorithms, and it should be noted that there are a number of other widely used algorithms for estimating expression on the basis of probe set intensities, including the method of Li and Wong in the dCHIP software package (Li and Wong, 2001) and the Robust Multichip Average algorithm (Irizarry *et al*., 2003) in the BioConductor suite of tools (**http://www.bioconductor.org**). Standardization has also enabled the development of quality control and standard operating procedures (QC/SOP). A recent publication explains standard QC/SOP suggestions for Affymetrix arrays, and the reader is referred to this publication for further explanations and metrics (Tumor Analysis Best Practices Working Group, 2004).

5. Project analysis software for microarray projects

Determination of numerical expression values (normalized "signal") for probe sets is the initial step to extracting biological information from Affymetrix array data. After definition of signals using one or more of the probe set algorithms, data analysis then turns to interpretation of the project (microarray comparisons) (*see* Article 57, **Low-level analysis of oligonucleotide expression arrays**, Volume 7). Typically, there are a number of biological replicates (two or more microarrays representing the same "group"; for example, a control or experimental group), and any number of groups within a project. A relatively simple project would have just two groups; for example, "normal muscle at rest" and "exercised muscle", with two or more replicates per group. This basic experimental design can be expanded to a time series (time points after a bout of exercise), or to multiple groups (endurance training, power training, weightless in space).

For an individual with considerable Microsoft Excel or other spreadsheet savvy, it is feasible to execute some manipulation of expression value data by writing and implementing one's own equations for normalization and statistical comparisons. However, because this is beyond the scope of many researcher's time and other constraints, and because the Affymetrix manufacturing consistency makes it possible, most array data analysis is executed with the assistance of software programs such as MAS5.0 (**http://www.affymetrix.com**), GeneSpring (**http://www.silicongenetics.com**), dCHIP (**http://www.biostat.harvard.edu/complab/dchip**), SpotFire (**http://www.spotfire.com**), and HCE (**http://www.cs.umd.org/hcil/hce**), among others. While there is a large degree of overlap in the features offered by each of these programs (as all endeavor to be stand-alone analysis packages), each tend to have their own strengths and can usually be used in combination to make use of these unique advantages. MAS5.0, GeneSpring, and SpofFire are commercially

available software packages, and the reader is referred to the corresponding website for more information. Here, we briefly describe two freely available software packages, dCHIP (Li and Wong, 2001) and HCE (Seo *et al*., 2004).

dCHIP software (**http://www.biostat.harvard.edu/complab/dchip**) focuses on calculating expression values and absolute calls (present/absent), but takes a "project-based" view, rather than a "single microarray" view. As such, it analyzes all microarrays within a project simultaneously, thereby detecting "chip outliers" (a microarray that is too dissimilar from others in the project), and providing project-based normalization. Whole project filtering is made possible allowing the user to create lists of genes that meet certain criteria. Filtering criteria offered in the current version of dCHIP include: selection of genes whose variation across all arrays falls within a certain range, selection of genes that are called Present in at least some minimum percentage of arrays, and selection of genes whose raw expression value exceeds a certain threshold in a certain percentage of arrays. This sort of filtering allows the user to pare away what is uninteresting from the 20 000+ probe sets for which data has been collected. In addition, dCHIP also allows the user more versatile tools for executing statistical comparisons of arrays. The user is able to specify any group of arrays to be compared to any other group of arrays and the program offers several different criteria by which to execute the comparison. The first selects genes which have a "fold change" greater than a specified value when the groups are compared (expression values within groups are averaged to execute the comparison). The second criteria selects genes with an absolute difference greater than or less than a specified threshold when the groups are compared. A third identifies genes that are called present in a at least a certain percentage of the groups being compared. The software also allows selection of genes with p-value less than a specified threshold as determined by either standard or paired t-test analysis. One major advantage of this statistical comparison package is that it allows several comparisons to be executed simultaneously through an option to combine comparisons. For example, the user could select all genes passing a certain fold change threshold between two groups that also pass a fold change threshold between two entirely different groups.

The outputs of all such filtering and statistical comparison executed in dCHIP are in the format of lists, which can be linked with ontological data for each probe set provided that the user downloads such information into the program. There are not, however, direct links to annotation data bases. Another limitation of the program is that there is no corresponding visual representation of these filtering and comparison results. dCHIP does contain a PM/MM data view interface that allows the user to obtain very detailed information about the behavior of each probe set, but the user must toggle between views to observe the behavior of any given probe set from one array to another. This sort of data visualization is more useful as a retrospective analysis tool to confirm the behavior of probe sets deemed to be interesting by the user via preliminary analysis within dCHIP or other analysis programs. dCHIP also contains an option for unsupervised sample and gene clustering.

HCE, or Hierarchical Clustering Explorer (**http://www.cs.umd.org/hcil/hce**) is focused on data visualization and interpretation, with the goal of optimizing human/computer interaction. It is a downstream analysis program in that it requires

prior calculation of expression values (signals) by another program. HCE also lacks a provision for filtering or comparison-based selection/exclusion of genes so this, too, if desired, must be executed prior to loading data into the program. Once data is loaded into HCE, it is normalized for visualization, with allowance for user adjustment. The main HCE display consists of sample or gene clustering. Before executing the clustering, the user is allowed to specify which linkage and similarity measures are to be used, how the dendrogram should be organized as it is being created, and which samples to include data from when executing the clustering. The main display is interactive, allowing the user to zoom in on heatmap/dendrogram areas of interest, and to hide features that are uninteresting. Such data display allows visual identification of gene expression patterns of interest such as a region of the heat map indicating upregulation of a cluster of genes in treatment but not in control samples and lists of the genes in regions of interest can be exported for further analysis.

The unique aspects of HCE that set it apart from other analysis programs are those referred to as “rank-by-feature” functions. These functions were implemented with the aim of simplifying multidimensional data analysis. Any data that has more than three dimensions (expression array data, economic trend data, etc.) becomes difficult to visualize and often interesting correlations and relationships among the various dimensions go unnoticed. HCE attempts to overcome this difficulty somewhat by assisting the user in executing a brief but thorough survey of the data to identify the “shape” of the data. To this end, the data can first be examined in one dimension with the program’s Histogram Ordering function. Within this function, the user examines histograms for each array, where each data point is representative of a single probe set expression value. These histograms can then be ordered according to criteria such as normality, uniformity, number of potential outliers, number of unique values, and size of biggest data gap. Color coding of lists allow the user to readily identify which arrays are at either extreme with respect to the currently selected criteria (i.e., which array has the most and which has the least normal histogram distribution). If a region of interest is noted on the histogram, it can be selected to determine the identity of the data points contained therein. Lists of data point selected in this manner can be exported, and the program interface also provides limited database links for selected data points.

From there, the user moves on to examine the data in two dimensions with the program’s Scatterplot Ordering function. In this function, dimensions, or arrays, are compared to one another, and the degree of their correlation, based on user selected criteria, is color-coded. The comparison criteria available to the user are the correlation coefficient, least square error for linear regression, quadracity, number of potential outliers, and number of potential items in a region of interest. As with the histogram function, scatterplots at either extreme of a given comparison criteria can be readily identified by the color-coding scheme and regions of interest can be selected for identity and database link information.

These rank-by-feature functions present both challenges and unique opportunities in the analysis of microarray data. Challenges include biological interpretation of a noted pattern or relationship. For example, if one finds that disease versus control comparisons have a very clear quadratic (as opposed to linear) correlation, what does this reveal about physiological processes of the disease? A unique opportunity

is found in the fact that this program has the potential to accept both array and nonarray data simultaneously and to look for correlations based on these criteria as well. This would be of particular advantage for an array project in which considerable clinical data (weight, age, height, etc.) was also available for each of the samples.

6. Practical hints regarding project analyses: false discovery rate correction, stats, fold change

Each microarray mRNA profiling project contains both "desired" experimental variables under study and potential "confounding" variables. The goal of any good experimental project is to control as many of the confounding variables as possible. For example, in experiments using mice, the sex, age, and mouse strain used are all potential confounding variables. This variation can be easily controlled (e.g., only mice of the same sex, age, and inbred mouse strain are utilized in the project). However, in human projects, these same variables can be much more difficult, if not impossible to control, and they become confounding variables.

Potential confounding variables in microarray experiments that require careful consideration include tissue heterogeneity (e.g., variability and sampling errors in use of small tissue samples) and variability in tissue culture conditions that may lead to differences between "identical" cultures. Though tissue culture is generally considered a very "clean" experimental system, variations in cell density, temperature, and media content can all lead to relatively dramatic changes in expression profiles. Another potentially significant source of confounding noise is technical variability in the processing of the RNA and arrays. However, use of quality control and standard operating procedures can reduce the technical variation to a level of relatively small concern (Tumor Analysis Best Practices Working Group, 2004).

In practice, it is often best to run *unsupervised clustering by chip* as the initial step in data analysis (see Seo *et al*., 2004). In this analysis, hierarchical clustering is used to determine which microarrays are most closely related in the pattern of signals over all probe sets (Figure 4). Ideally, one should find that the microarrays in a project are grouped in the dendrogram by the desired biological variable. An example of this is shown in Figure 4, where inbred mice injected with lipopolysaccharide (LPS) were sacrificed and exsanguinated at defined time intervals (0, 24, 48 h). Specific cell types (T_H1, T_H2, and platelets) were then isolated from the peripheral blood using a negative cell isolation technique (StemCell Technologies, Inc). Two rounds of RNA amplification were performed, and the resulting microarrays clustered by sample (Figure 4). It can be seen that the T_H1 samples at 24 and 48 h form the left-most branch, while T_H2 samples (0, 24, 48 h) form a cluster in the center of the dendrogram. The platelet profiles (PLT) seem more variable, with two samples clustering among T_H1 samples and two more distantly related samples forming their own branches to the right of the dendrogram. One could surmise that the microarrays from the T_H1 and T_H2 cell populations are relatively consistent within each group, while the platelets are

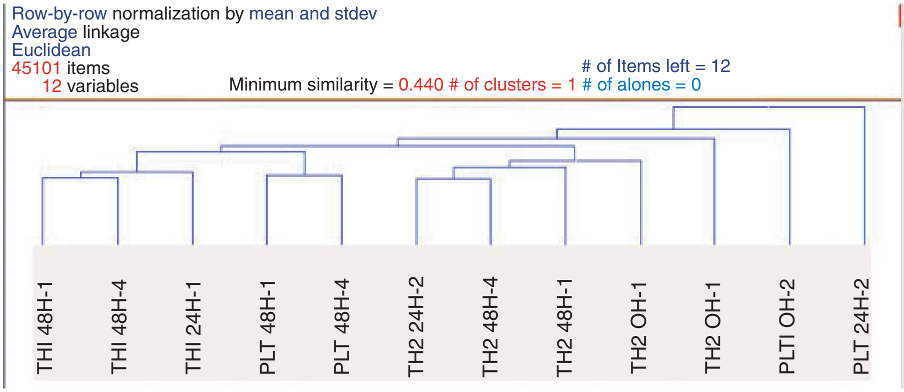

Figure 4 Unsupervised hierarchical clustering to determine extent of confounding variables. In this experiment, mice were exsanguinated at three time points (0, 24, 48 h) following LPS injection. Three different cell types (T_H1, T_H2, and platelets [PLT]) were then purified from the blood. Unsupervised hierarchical clustering of arrays was performed using HCE, resulting in the dendrogram (tree) shown below. This figure is further interpreted in the chapter text above. Note that the T_H1 and T_H2 cell arrays generally cluster together, while the platelet profiles are less consistent in locus within the dendrogram. This analysis suggests that there are more uncontrolled confounding variables with platelets, and that resulting data should be considered "noisy" in nature. An alternative interpretation would be that platelets at 48 h take on many features of T_H1 cells. More replicates would be needed to distinguish between these possibilities

more variable. This suggests that there is less uncontrolled confounding noise with T_H1 and T_H2 cells, compared to platelets and that the findings of the T_H1 and T_H2 data are likely more reliable than the platelet data. As follow-up, one could reassess platelet preparation purity and otherwise attempt to identify variables in the procedure that are contributing to confounding noise in platelet samples. In general, the better the unsupervised clustering appears (e.g., unsupervised segregation into the known biological groups), the cleaner and more robust the resulting data interpretation will be (e.g., upregulated and downregulated transcripts).

Another generalization is that it is best to calculate expression values using two different probe set algorithms (e.g., MAS5.0 and dCHIP difference model), to execute all statistical group comparisons using both sets of expression values in parallel, and to rank all resulting data by significance (p-value) between groups. It is best to rank by p-value rather than by fold change because large fold changes can have no significance (high variability), while small changes can show very strong p-values. Those transcripts that show consistent comparison results (fold change and p-value) with both MAS5.0 and dCHIP can be considered the most robust and prioritized for follow-up. Other transcripts may show a very strong p-value with one algorithm, and not the other; these can be assigned to the next tier of confidence. It is not unusual to find only 10–30% concordance between data obtained from different probe set algorithms. Concordance, as one might expect, decreases as experimental noise (uncontrolled confounding variables) increases.

A very active area of debate within the research community is how to best correct for multiple testing in microarray data analyses. Clearly, when one is testing millions of oligonucleotides, and tens of thousands of probe sets, a p-value of 0.05 is likely to identify many "differences" by chance, as 5% of the 40 000 probe sets

on an array is 2000 probe sets. There is no easy answer to the "multiple testing" problem. However, there are three pragmatic ways around this issue. First, use of a different method/platform (such as quantitative RT-PCR) to validate or confirm the transcripts of interest (ideally using a distinct sample set). A second option is to examine only a small subset of the data. For example, if one is interested in cytokines and only considers the probe sets for cytokines, the 40 000 probe sets at hand could be reduced to a few hundred, lessening the concern about multiple testing. Finally, statistical corrections can be applied to account for multiple testing, but these increase specificity by reducing sensitivity and in reality select only those p-values that are most significant without changing their overall ranking.

7. Practical hints on experimental design

A major challenge in microarray projects is to obtain the maximum sensitivity and specificity, which can be accomplished by removing all or most potential confounding variables, and/or by increasing replication. Data analysis always entails balancing of signal/noise issues, and few clear definitions exist for minimum number of replicates that should be used in microarray investigation. Some generalizations can be made; inbred mouse projects using whole organs require relatively few replicates (often as few as $n = 3$ per group), whereas human tissue experiments, with numerous confounding variables, require much larger groups. This paradigm serves to make a project using mice reasonable in scope and cost, and the equivalent project using human samples much more daunting (and noise-ridden).

One way to avoid the many uncontrolled confounding variables in human studies is longitudinal sampling. If multiple blood samples are taken from the same person, then each person serves as his own control, and the effects of uncontrolled variables such as ethnicity, age, and sex, can be minimized. For example, we have studied muscle biopsies from volunteers in an aerobic training program, with four muscle biopsies taken per subject (Hittel *et al*., 2003; Hittel *et al*., 2005). The longitudinal design allowed robust data to be obtained from just three males and three females.

One last practical note is that rats and knockout transgenic mice are typically "out-bred". Thus, one cannot assume that littermates are genetically identical, and interindividual variation becomes a major confounding variable, as it is in humans.

8. Database resources

A large amount of Affymetrix microarray data is publicly available at three databases; NCBI GEO (**http://www.ncbi.nih.gov/geo**), ArrayExpress (**http://www.ebi.ac.uk/arrayexpress**), and PEPR (Public Expression Profiling Resource; **http://pepr.cnmcresearch.org**). GEO and ArrayExpress contain many types of experimental platforms (spotted microarrays, SAGE, Affymetrix arrays, other), while PEPR is an Affymetrix-only resource. To build cross-platform databases, an international consortium was formed to develop a consensus regarding key information

required for each microarray experiment; namely, the MIAME guidelines (Minimal Information About a Microarray Experiment) (**http://www.mged.org**; Brazma *et al*., 2001). Consistent with the MIAME standards, many scientific journals require that microarray data discussed in publications be made publicly available with sufficient information to allow interpretation.

University of Pennsylvania, Philadelphia, PA, USA

1. Introduction

Comparative genomic hybridization (CGH) is a molecular cytogenetic method for detection of chromosomal abnormalities. In a CGH experiment, differentially labeled "test" and "reference" DNA samples are simultaneously hybridized to "target" DNA sequences bound to glass slides (Figure 1). The basic assumption of a CGH experiment is that the ratio of the binding of test and control DNA is proportional to the ratio of the concentrations of sequences in the two samples. So the intensity ratio of the two fluorescence signals is indicative of the relative DNA copy number in the "test" relative to the "reference" DNA sample. Traditionally, CGH is performed using metaphase chromosome targets (it is referred to as *chromosome* CGH). This technique has contributed significantly to the current understanding of gross chromosomal imbalances and variations associated with certain diseases, particularly cancer, since regions of amplifications and deletions are likely to contain novel oncogenes and tumor suppressor genes (reviewed in Lichter *et al*., 2000). Although chromosome CGH allows genome-wide analysis of gross DNA copy number imbalances, there are two major limitations that restrict its usefulness as a comprehensive screening tool. First, CGH to metaphase chromosomes provides only limited resolution in the identification of deletions and gains, which is at best is in the order of 2–10 Mb (Lichter *et al*., 2000). In addition, chromosome CGH cannot be easily automated because of the need to identify individual chromosomes. Recent advances in microarray technology allow one to circumvent these limitations by replacing metaphase chromosomes with a collection of mapped cDNA clones, oligonucleotides, or genomic clones placed on glass slides (Solinas-Toldo *et al*., 1997; Pinkel *et al*., 1998; Beheshti *et al*., 2002). This new platform for genome-wide analysis of chromosomal imbalances is generally referred to as *microarray* CGH. Yano and colleagues have recently determined that although gains and losses of DNA sequence copy numbers detected by array CGH and conventional CGH coincided highly, with correspondence rates of 94 and 95%, respectively, microarray CGH had higher sensitivity for the detection of copy number losses compared with that for conventional CGH (Yano *et al*.,

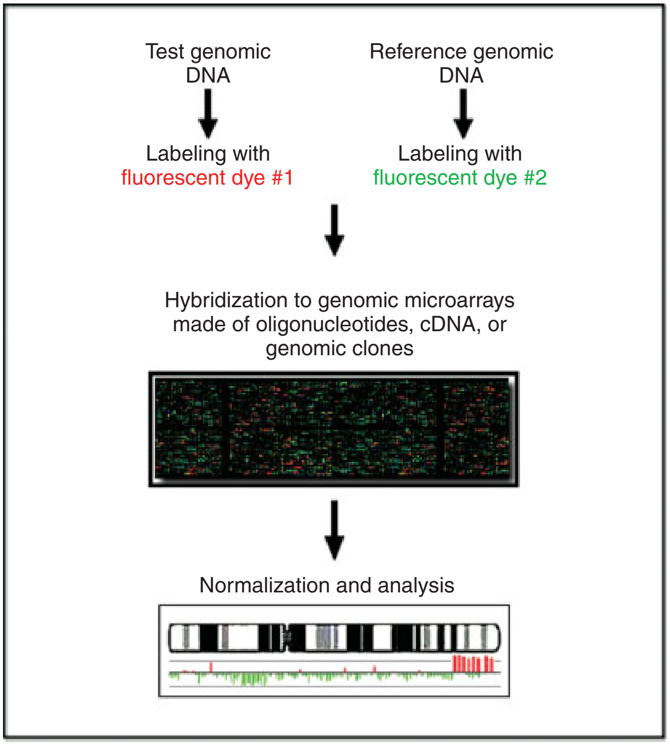

Figure 1 Schematic diagram of a typical microarray CGH experiment. Differentially labeled "test" and "reference" DNA samples are simultaneously hybridized to DNA sequences bound to glass slides. The intensity ratio of the two fluorescence signals is indicative of the relative DNA copy number in the "test" relative to the "reference" DNA sample

2004). In an earlier study, it was also observed that despite overall concordance between results obtained with microarray CGH and conventional CGH, not all amplified genes detected by microarrays CGH were detected by chromosome CGH (Arai *et al*., 2003). These results can be potentially explained by higher resolution achieved by microarray CGH platforms (currently down to 30∼70 kb), which is significantly higher than that of conventional CGH (Lucito *et al*., 2003; Ishkanian *et al*., 2004). This article will focus on current techniques utilized to manufacture microarrays for CGH analysis. We will also discuss approaches that are used to prepare and hybridize labeled genomic DNA probes and methods employed in analysis of microarray CGH hybridization experiments.

2. Microarrays for comparative genomic hybridization

Currently, there are three major approaches for manufacturing microarrays for genomic hybridizations: cDNA array CGH, oligonucleotide array CGH, and BAC array CGH.

2.1. cDNA array CGH

In cDNA array CGH, one utilizes conventional cDNA arrays, such as those used in gene expression studies. The utility of this approach was first demonstrated by Pollack *et al*. (1999). They used a 3360-feature cDNA microarray platform to perform parallel CGH and gene-expression studies on a collection of breast cancer cell lines and tissues. This approach allowed them to study relationships between gene amplification and overexpression. Later on, Pollack and colleagues expanded their initial gene expression/copy number alteration profiling study to 44 advanced, primary breast tumors and 10 breast cancer cell lines by using cDNA microarrays containing 6691 different mapped human cDNAs (Pollack *et al*., 2002). Similarly, Guo *et al*. (2002) utilized a 21 632-feature cDNA microarray to profile gene expression and copy number alterations in nasopharyngeal carcinomas. Beheshti *et al*. (2003) performed CGH analysis of 10 neuroblastomas using a 19 200-feature cDNA microarray. cDNA CGH approach offers several advantages. The most important one is the availability of a significant number of commercial cDNA array platforms and cDNA clone sets. In addition, with ever-increasing characterization of a complete human gene set, cDNA array CGH can serve as a useful tool for direct identification of genes in the amplified and/or deleted regions. Finally, as mentioned above, cDNA arrays have an advantage in allowing analysis of DNA copy number alterations and mRNA expression of the same genes in the same sample through easy parallel hybridizations experiments. However, there are several major limitations of this approach. First, cDNA sequences do not represent any intergenic sequences such as introns and promoter sequences, where potential alterations can occur. Even a complete set of full-length cDNA clones will represent at best only 5% of human genomic sequences. Also, because of the small size and reduced complexity of the cDNA target sequences, cDNA array CGH approach may not have sufficient sensitivity to reproducibly detect low copy number imbalances (Beheshti *et al*., 2002; Beheshti *et al*., 2003). Beheshti *et al*. (2003) estimated that deletions or copy number gains below the level of 10 to 20 copies cannot be determined with certainty. Finally, there is an extensive sequence similarity between paralogous genes (gene families), which can interfere with the interpretation of cDNA array CGH data.

2.2. Oligonucleotide array CGH

A second, and currently the least utilized, approach for manufacturing genomic microarrays involves oligonucleotides. Recently, three reports were published that utilized microarrays made of oligonucleotides for high-resolution detection of copy number changes (Lucito *et al*., 2003; Bignell *et al*., 2004; Zhao *et al*., 2004). Lucito *et al*. (2003) arrayed 70-mer oligonucleotide probes designed from the human genome sequence with an average resolution of a probe every 30 kb and determined copy number alterations in genomic DNA samples from cancer cells. In their experiments, differentially labeled "test" and "reference" DNA samples were simultaneously hybridized to the 85 000 feature oligonucleotide arrays. In a different approach, two groups utilized commercially available SNP detection microarrays (like Affymetrix GeneChip 10 000 SNP assay; **http://www.affymetrix.com**)

for copy number changes detection (Bignell *et al*., 2004; Zhao *et al*., 2004). Current resolution of this microarray is approximately 210 kb on the genome. Affymetrix has recently released a 100 000 SNP GeneChip that increases resolution to ~20 kb. This approach also produces genotyping data in conjunction with the copy number alterations analysis.

It should be noted that all groups utilized a “genomic complexity reduction” approach when preparing genomic DNA samples for hybridization (Lucito *et al*., 1998). Genomic DNA samples were digested to completion using BglII or Xba1 prior to ligation of adaptors and amplification of the ligation products using an adaptor-specific primer (Lucito *et al*., 2003; Bignell *et al*., 2004; Zhao *et al*., 2004). Oligonucleotide probes on microarrays utilized by all groups were specifically selected to represent genomic sequences in the vicinity of BglII or Xba1 restriction endonuclease sites that will be amplified using a “genomic complexity reduction” method. This approach was shown to reduce the complexity of the genome by 98% and thereby improve hybridization kinetics since it produces more copies of particular sequences within a given mass of DNA that are complimentary to the arrayed oligonucleotides (Lucito *et al*., 1998).

Oligonucleotide genomic arrays offer several advantages. First, they provide very high resolution coverage of human genome. Because of the small size of oligonucleotide probes, they can observe very small deletions and amplifications that would be missed with high-density BAC since size of the BAC (150–200 kb) obscures high resolution. Since sequence composition of oligonucleotide arrays is precisely specified, these arrays can be easily converted into highly reproducible fabricated industrial standard product that can be made available for wide usage. One of the disadvantages of oligonucleotide arrays is their high production cost and limited availability. Another disadvantage of oligonucleotide array is their current reliance on “genomic complexity reduction” methodology. Some genomic sequences will be poorly represented by this approach because of lack of particular restriction endonuclease sites in certain regions. Polymorphism of restriction endonuclease sites also presents a challenge in interpretation of CGH data (Lucito *et al*., 2003).

2.3. CGH with arrays made of genomic clones

The third and most frequently used microarray CGH platform uses genomic DNA derived from genomic clones such as yeast artificial chromosomes (YAC), bacterial artificial chromosomes (BAC), P1, PAC, and cosmids as targets on the microarray. Very frequently, when people mention microarray CGH they refer to CGH analysis that utilizes microarrays made of genomic clones. This array CGH platform was first described by Solinas-Toldo *et al*. (1997). Early experiments with genomic microarrays were limited by the absence of good collections of mapped clones and therefore utilized small collections of mapped cosmids, P1, YAC and BAC (Solinas-Toldo *et al*., 1997; Pinkel *et al*., 1998). Since then, our laboratory and several other groups had assembled several collections of mapped BAC clones spanning the human genome at an average interval of ~1 Mb (Morley *et al*., 2001; Cheung *et al*., 2001; Snijders *et al*., 2001; Fiegler *et al*., 2003). For example, we

have assembled in our laboratory a collection of about 5000 mapped RPCI-11 BAC clones that covers the human genome at approximately 1-Mb resolution (Morley *et al*., 2001; Cheung *et al*., 2001; Smirnov *et al*., 2004a). The clones were anchored to STS markers from the GeneBridge 4 radiation hybrid map. Each clone was mapped by filter hybridization and verified by PCR to contain the STS marker. Chromosomal locations of some of the clones were verified by fluorescent in situ hybridization (Kirsch and Reid, 2000). The mapped clones were further characterized by HindIII fingerprinting and end-sequencing. The clones were anchored to the current human genome sequence assemblies by aligning the end sequences of the BAC clones to the DNA sequences at the UCSC Genome Browser. Information about the mapped BAC clones is available through our Web-based database GenMapDB, **http://genomics.med.upenn.edu/genmapdb** and through the UCSC Genome Browser (**http://genome.ucsc.edu** on the GenMapDB clone track). Glycerol stocks of all the clones are available through various repositories (**http://genomics.med.upenn.edu/genmapdb**). Recently, this collection was expanded by groups at Genome Sciences Centre, Vancouver, BC, Canada, and BACPAC Resource Center at Children's Hospital Oakland Research Institute in Oakland, California. They have assembled a collection of 32 433 BAC clones that covers the entire human genome at a final resolution of ∼75 kb (Ishkanian *et al*., 2004). The identity of all the clones has been validated by fingerprinting. Information about this collection is available at **http://bacpac.chori.org/pHumanMinSet.htm**. This collection of BAC clones was recently arrayed on glass slides, and successful array CGH experiments were performed (Ishkanian *et al*., 2004).

2.3.1. Strategies for construction of microarrays made of genomic clones

Despite the availability of mapped clones, the manufacturing of genomic microarrays is still challenging because of the difficulty of preparing adequate amounts of DNA from genomic clones (Beheshti *et al*., 2002). Initially, for microarray CGH studies, DNA from genomic clones was extracted using a large-scale alkaline lysis method followed by the anion-exchange chromatography (Solinas-Toldo *et al*., 1997; Pinkel *et al*., 1998). When expanded to thousands of clones, this approach becomes too labor intensive and expensive. Unfortunately, small-scale DNA preparations do not produce sufficient amounts of genomic DNA to manufacture genomic microarrays. In addition, *E. coli* DNA is a very common contaminant of DNA preparations from large insert clones using small-scale silica- or filtration-based DNA preparation miniprep kits (10–25% of total purified DNA) (Foreman and Davis, 2000). There are currently three strategies that are used to manufacture large genomic microarrays. All these procedures involve amplification step that aims at producing large quantities of DNA from a library of clones, and generating spotting solutions with high DNA concentration sufficient for microarray manufacturing. The first strategy utilizes degenerate oligonucleotide primer (DOP) PCR that is designed to amplify representative fragments of the BAC DNA with degenerate primers in a single step (Telenius *et al*., 1992). Recently, Fiegler *et al*. (2003) used a bioinformatic approach to select three novel degenerate DOP-PCR primers primers that were efficient in the amplification of human DNA but were poor at amplifying

E. coli DNA, a common contaminant of DNA preparations from large insert clones. Using this approach, a BAC array was constructed that covers entire human genome at about 1-Mb intervals. Similar mouse-specific DOP primers were also designed and a 1-Mb mouse genome microarray was constructed (Chung *et al*., 2004).

Another strategy that is utilized for manufacturing large genomic arrays involves ligation-mediated (LM) PCR. LM-PCR starts with restriction enzyme digestion and linker ligation prior to two rounds of PCR amplification. This approach requires initial affinity chromatography-based purification of BAC DNA and does not prevent potential amplification of contaminating *E. coli* DNA. DNA preparations are monitored for contamination with *E. coli* DNA by gel electrophoresis prior to linker ligation (Snijders *et al*., 2001). LM-PCR approach was successfully used to manufacture very large genomic arrays (Snijders *et al*., 2001; Ishkanian *et al*., 2004).

A third strategy that is used for manufacturing genomic arrays employs strand-displacement rolling circle amplification (RCA) methodology. This technique utilizes random primers and Phi29 DNA polymerase to amplify circular DNA templates selectively and exponentially even in the presence of contaminating bacterial genomic DNA (Dean *et al*., 2001). This approach does not require thermocyclers and initial purification of BAC DNA. Recently, large genomic microarrays made of 4500 BAC clones were prepared using this technique (Smirnov *et al*., 2004a).

There are several other ways that can be potentially used for manufacturing large genomic arrays. GenomePlex Whole Genome Amplification technology developed by Rubicon Genomics can be potentially used to amplify BAC DNA to make large genomic arrays (Gribble *et al*., 2004). In about 3 h, microgram quantities of DNA can be generated from nanograms of starting material. Potentially, T7-based linear amplification system recently adapted for genomic DNA can also be used for preparation of BAC DNA for genomic array manufacturing (Liu *et al*., 2003). Also, inter-Alu PCR was utilized to manufacture large genomic arrays (Cheung *et al*., 1998; Smirnov *et al*., 2004b). This technique involves the amplification of a specific DNA region present between two nearby Alu sequences on the genome. Its principle is based on the widespread distribution of so-called Alu sequences (about 300 bp in size) among the human genome. There are about one million copies of it spaced along the genome about every 4 kb. Human DNA sequences can be selectively amplified using suitable Alu-primer pairs even in the presence of contaminating genomic DNA such as *E. coli* genomic DNA.

Genomic microarrays made of genomic DNA derived from genomic clones are currently most widely used platform for array CGH experiments. It offers excellent, potentially even complete representation of all human genomic sequences, making it very powerful for high-resolution CGH as well as other applications, such as chromatin precipitations (ChIP) and methylation status studies. However, this platform also has several disadvantages. As mentioned above, genomic microarrays made of large number of genomic clones are still difficult to manufacture. Some genomic clones contain repetitive sequences, which can lead to erroneous hybridization patterns. This problem can be particularly severe for certain repeat-rich regions of the genome. Large quantities of Cot-1 DNA have to be added to hybridization reactions to suppress hybridization of repetitive sequences. Certain

genomic clones may also represent duplicated regions in the genome that may complicate interpretation of hybridization results. Finally, large size of genomic clone also can potentially mask detection of small copy number abnormalities.

3. Probe preparation and hybridization to microarrays

Prior to microarray CGH experiment, genomic DNA isolated from "test" and "reference" samples are differentially labeled by incorporation of fluorescently labeled nucleotides, for example, Cyanine-3 and Cyanine-5 dCTPs. Sufficient amounts of starting genomic DNA (typically in a range of 50–500 ng per sample per hybridization) is required to perform hybridization to microarray slides. There are numerous instances where only a very small number of cells are available for cytogenetic evaluation. Considerable efforts are being directed toward utilization of whole genome amplification (WGA) methodologies to allow CGH analysis when only very few or even single cell is available for analysis. Many of the methods that are being utilized for manufacturing genomic arrays are also employed for unbiased amplification of very small amounts of "test" genomic DNA for CGH experiments. These methods include degenerate oligonucleotide primed PCR (DOP-PCR), primer extension PCR (PEP), phi29 strand-displacement rolling circle amplification (RCA), and OmniPlex technology (Zhang *et al*., 1992; Telenius *et al*., 1992; Dean *et al*., 2002; Barker *et al*., 2004). Recent amplification fidelity studies indicate that two methods, RCA and Omniflex, amplify genomic DNA in a highly representative manner (Dean *et al*., 2002; Barker *et al*., 2004; Paez *et al*., 2004). Unfortunately, these studies were not extended to samples with very small amounts genomic DNA (in pg range) to demonstrate the fidelity of amplification of genomic DNA sampled extracted from single cell. Following the preparation of differentially labeled "test" and "reference" samples, hybridization is performed to microarray slides in the presence of high concentrations (10 μg or more) of human Cot1 DNA to suppress nonspecific hybridization to repetitive sequences.

4. Analysis of microarray CGH data

In a typical microarray CGH experiment, the test genomic samples are labeled with one fluorescent tag (Cy3 dye, for example) and co-hybridized with a control sample labeled with a second fluorescent tag (Cy5 dye, for example). The fluorescent intensity ratios of each clone produced by hybridization of differentially labeled experimental and control genomic DNAs to the array are used as an indication of copy number changes. The ratio of experimental to control fluorescence is proportional to the relative dosage between the two samples. Since the samples hybridized to the microarrays were labeled with two different dyes, Cy3 and Cy5, that have different incorporation efficiency, it is often necessary to normalize the signal intensities. A method that is used frequently in microarray data analysis is to normalize all the Cy3 and Cy5 intensities to the value of one, assuming that the overall differences between the two channels are negligible. However, this global normalization method is not appropriate for many CGH experiments, especially

those with tumor samples that have high percentages of chromosomal aberrations (Wessendorf *et al*., 2002). Normalization based on regions that are known to have normal chromosome profiles is more precise but requires prior knowledge of the copy number changes in that sample. Alternatively, the rank invariant normalization method can be used, which allows one to perform normalization without prior knowledge of the degree of chromosomal aberrations in the samples (Tseng *et al*., 2001). In this method, normalization is based on clones whose rankings by intensity signal in the two channels are the most similar. These clones most likely represent regions with normal chromosomal profiles.

After normalization, the fluorescence ratio between experimental (test) and control genomic DNA (reference) samples should be 1.0 in regions where the relative DNA sequence copy number is the same in those samples, greater than 1.0 if the relative DNA sequence copy number in the test sample is greater, and less than 1.0 in regions where the relative DNA copy number is lower in the test sample. CGH profiles are interpreted by comparing the fluorescence intensity ratios of each clone to the "normal" ratio of 1.0 (reviewed in Molinaro *et al*., 2002). One method of interpretation of array CGH data is by deviation of the ratio from the thresholds of 1.25:0.75 (above or below threshold) (Wessendorf *et al*., 2002). A different method uses a standard deviation of replicate measurements obtained from reference to reference hybridizations to establish threshold levels. Deviations of the fluorescence ratio above or below the mean +/- 2SD are considered as significant changes in copy number (Schwaenen *et al*., 2004). Alternatively, a t-statistic (or nonparametric alternatives such as Wilcoxon Rank Sum Test) can be used to compare replicate fluorescence ratio measurements obtained from a test:reference CGH analysis with the results of reference:reference CGH hybridizations (Moore *et al*., 1997; Smirnov *et al*., 2004a). Several software packages (e.g. See GH; **http://www.bccrc.ca/cg/ArrayCGH_Group.html**) have been developed to help researchers to normalize, analyze, and visualize fluorescence data from array CGH experiments.

Analysis of CGH results obtained with oligonucleotide arrays offers a unique set of challenges. For example, CGH method based on Affymetrix SNP GeneChip differs from spotted-array-based CGH in that the normal and tumor DNAs are hybridized to different arrays in a similar fashion to Affymetrix expression array experiments. However, this approach still requires a set of separate experiments with genomic DNA from "normal" donors for the subsequent analysis of tumor samples (Bignell *et al*., 2004). In addition, when estimating copy number, the output from the each feature is often considered in the context of signal intensities from oligonucleotides in neighboring or flanking positions.

5. Applications of array CGH and genomic array technology

Microarray CGH is a very powerful method that allows detection and localization of DNA copy number aberrations, such as deletions and amplifications. From numerous traditional chromosome CGH experiments, it is apparent how widespread copy

number alterations are in cancer and other diseases (reviewed in Beheshti *et al*., 2002; see SKY/M-FISH and CGH database **http://www.ncbi.nlm.nih.gov/sky/**; Tumor CGH database **http://amba.charite.de/~ksch/cghdatabase/start.htm**; Database of Recurrent Chromosomal Aberrations in Cancer **http://cgap.nci.nih.gov/Chromosomes/RecurrentAberrations**). Microarray CGH allows improved high-resolution quantitative assessment of copy number changes. Array CGH genome analysis techniques have already revealed numerous regions that are frequently abnormal in multiple types of tumors. Several well-established oncogenes, tumor suppressor genes, and genes associated with cancer susceptibility have been mapped to these regions of recurrent abnormality. These include MYC (amplification at 8q24), AKT2 (amplification at 19q13), ERBB2 (amplification at 17q21.2), CCND1 (amplification at 11q13), p53 (deletion at 17p13), BRCA1 (deletion at 17q21), and BRCA2 (deletion at 13q12); BCL2 (amplification at 18q21) (Forozan *et al*., 2000; Pollack *et al*., 2002; Ishkanian *et al*., 2004; Smirnov *et al*., 2004a). These data strongly support the notion that regions of recurrent abnormality encode genes that contribute to cancer progression when differentially expressed because of mutation, loss, or amplification. Increased resolution of array CGH will facilitate identification of new genes in specific chromosomal regions and functional characterization of already-known genes. Similarly to cDNA array gene expression profiling, CGH profiles of cancer samples also have a potential to be used to predict survival and choose treatment (van't Veer *et al*., 2002). Diseases and conditions other than cancer will also benefit from recent advances in microarray technology. For instance, Shaw-Smith and colleagues employed DNA microarray to identify copy number changes in patients with learning disability and dysmorphism (Shaw-Smith *et al*., 2004). Hu *et al*. (2004) used arrays to screen for evidence of aneuploidy in single cells. Thus, microarray CGH technology could also potentially be used for analysis of preimplantation embryos, uncultured amniocytes, and single fetal cells isolated noninvasively from peripheral blood of pregnant women.

In addition to array CGH, genomic array technology can have a utility in other areas of genomics. Genomic microarrays can be used to identify promoter sequences isolated by chromatin immunoprecipitations (reviewed in Buck and Lieb, 2004). Genomic microarrays can also be used to identify genomic sequences and genes regulated through epigenetic modification (Ballestar *et al*., 2003). Genomic arrays were successfully used for mapping regions shared identical-by-descent (IBD) between two individuals without locus-by-locus genotyping or sequencing (Cheung *et al*., 1998; Smirnov *et al*., 2004b). Recently, a technique named *genomic microarray painting* was described that allows high-resolution analysis of composition and the breakpoints of aberrant chromosomes (Gribble *et al*., 2004). Several new technologies, such as multiplex amplifiable probe hybridization (MAPH) and multiplex ligation dependent probe amplification (MLPA), when combined with genomic microarrays have the potential to provide sensitive and precise targeting of the unique regions of the genome where rearrangement occurs (Hollox *et al*., 2002; Schouten *et al*., 2002). In the next several years, these and other applications of genomic microarrays will be developed for basic research and clinical applications.

6. Remaining challenges

Despite enormous progress and promise, many obstacles remain in the way of genomic microarrays to become a clinical diagnostics tool. When compared to expression arrays, it is clear that in the field of genomic microarrays there are still no widely accepted commercial genomic array platforms. In fact, only few companies offer genomic microarray products. For clinical applications, it is essential that all of the targets placed onto genomic arrays were extensively characterized. For instance, all BAC clones will have to be FISH-mapped to reveal mismapped clones and those that hybridize to multiple sites within human genome. Moreover, precise standards for signal normalization and genomic microarray data analysis are yet to be established. When working with very small amounts of DNA from clinical samples (picogram range), methods utilized for whole genome amplification are yet to be extensively characterized. Finally, extensive clinical evaluations will have to be performed in order for the microarray CGH technology to be widely accepted as a routine diagnostic tool.

Specialist Review

Expression and localization of proteins in mammalian cells

Jennifer L. Stow and Rohan D. Teasdale
The University of Queensland, Brisbane, Australia

1. Introduction

The ability to transfer foreign DNA into eukaryotic cells for the expression of recombinant genes and proteins has revolutionized experimentation in biology and has created new approaches for the treatment of genetic disease in humans. Basic molecular biology techniques allow engineering of DNA to dictate the conditions and locations of gene expression, to alter the form and function of gene products, and to tag gene products in any number of ways. The techniques of cell biology then come to play in analyzing the subcellular location of a specific gene product, its function within cells and whole organisms, and its role in disease. Genome enterprises present us with large cohorts of known and novel genes. At the cutting edge of dissecting the biology of whole genomes is our ability to harness the forces of molecular and cellular biology for the large-scale, high-throughput expression of genes, and the analysis of protein location and function in fixed cells or in living cells and organisms.

This review will focus on the methodologies for gene transfer and protein expression in mammalian cells, and on the emerging technologies for high-throughput analysis of in vitro protein expression. One important end point for the development of gene transfer and protein expression techniques is their application to gene therapy with the goal of curing, treating, or circumventing defects in genetic disease in humans. This is a field of intense investigation and one that is constantly and thoroughly reviewed in the literature (Chernajovsky *et al*., 2004; Scollay, 2001). The production of biopharmaceuticals represents another emerging application for recombinant gene technology (van Berkel *et al*., 2002). However, this current review will focus on experimental applications of gene and protein expression and the move toward high-throughput application of these techniques.

2. Methods for gene expression – many ways in, on, and off

Molecular and cellular biology have provided us with the means to introduce foreign genes into eukaryotic cells in order to express recombinant proteins for many applications in research, agriculture and medicine. While typically applied to

the analysis or production of single recombinant gene products, there is increasing need for large-scale gene or protein expression to analyze whole genomes and proteomes. The vectors and methods for introducing foreign DNA into mammalian cells have been continuously refined over the past two decades to improve the efficiency of transfection, the levels of expressed protein, and to manipulate the timing, location, and stimuli for gene expression. Much of this development has been driven by the need to obtain ultimately safe and effective expression systems for gene therapy, with research applications reaping benefit along the way.

A variety of physical, chemical, and biological approaches have been exploited for introducing recombinant genetic material and proteins into cells (see Table 1). There are pros and cons to each of these methods, and the method of choice in any situation is based largely on the type of cell being transfected and the goal of the expression (Colosimo *et al*., 2000). For experimental purposes, perhaps the most commonly used techniques utilize a wide range of commercially available cationic

Table 1 Summary of methods used for transfection and gene expression in mammalian cells

Method	References
Calcium phosphate	
One of the earliest transfection methods. Coprecipitates of calcium phosphate and DNA are added to and taken up by cells. This plasmid method allows simultaneous transfer of multiple DNA constructs for coexpression.	Kato *et al*. (1986) Batard *et al*. (2001) Jordan and Wurm (2004)
Physical methods	
Purified plasmid DNA can be directly micro-injected into the nuclei or cytoplasm of individual mammalian cells; up to hundreds of cells can be injected. GFP-tagged gene products can be visualized immediately upon synthesis and imaged in live individual cells.	Boyd (2002) Kreitzer *et al*. (2003) Trezise (2002) Li (2004)
Electroporation techniques use electric current to transiently perforate cells or in vivo tissues for entry of plasmid DNA. Electroporation is used for cell types that are not amenable to transfection by other methods and for multiple transgene transfer to large numbers of cells.	
Lipofection	
Synthetic, cationic lipids mixed with plasmid DNA to form liposomes that fuse with or are taken up by cells. Many liposome formulations are now commercially available and offer wide-ranging functionality and efficient transfer in experimental systems and in some clinical situations.	Felgner *et al*. (1987) Safinya (2001) Tranchant *et al*. (2004)
Viral vectors	
Designer, recombinant viral vectors with packaged transgenes but excluding virally encoded genes give high efficiency transfer and high levels of protein expression. Vectors based on adenoviral and adeno-associated DNA viruses are the most commonly used to date for gene therapy, infecting a wide range of cell types. Vectors based on RNA retroviruses integrate stably into the host genome for sustained transgene expression. Lentiviral vectors such as HIV-1 infect both dividing and nondividing cells.	Cepko *et al*. (1984) St George (2003) Delenda (2004) Blesch (2004) Lu (2004)

liposome formulations as vehicles for inserting DNA plasmids into mammalian cells (Safinya, 2001; Tranchant *et al*., 2004). Viral vectors, which make use of the inherent propensity of viruses to invade mammalian cells, are undergoing the most intense refinement for potential therapeutic use in humans. Of note are the lentiviral vectors, particularly those based on HIV-1, which hold promise for highly efficient, stable, and safe expression of recombinant proteins in many cell types and tissues for research purposes, and in the clinic (Blesch, 2004; Delenda, 2004).

The plasmids for introducing recombinant DNA into mammalian cells are also under constant development. Viral promoters such as the cytomegalovirus early promoter (CMV) were first introduced to drive the constitutive, medium-level expression of genes in mammalian cells, and other viral promoters offer either higher or lower levels of constitutive expression (Fitzsimons *et al*., 2004). An important advance was then in the development of plasmids for regulated gene expression. Regulatory elements from the bacterial *lac* operator and repressor provide tight, reversible expression of genes normally involved in lactose uptake and metabolism, but can be utilized for inducible expression of transgenes in mammalian cells. As a readily visible demonstration of how the *lac* operator-repressor system works, Cronin *et al*. (2001) used it to drive IPTG-inducible expression of an exogenous tyrosinase gene in mice, which in turn resulted in inducible coat-color variation (Cronin *et al*., 2001). The tetracyclin resistance operon from *Escherichia coli* is the basis for *tet*-inducible expression in mammalian cells (Knott *et al*., 2002) by which gene expression can be turned on or off. Hormone-based inducible expression systems, namely, progesterone and estrogen make use of ligand-binding nuclear hormone receptors to switch transgene expression on and off (Evans, 1988). Viral plasmids can be engineered in a variety of sophisticated ways to give targeted insertion into the genome and to regulate gene expression (Galla *et al*., 2004; Grez and von Melchner, 1998; Tan *et al*., 2004). Expression of specific proteins in whole animals, especially for gene therapy purposes, relies on the use of customized plasmids, often with promoters to drive cell- or tissue-specific expression and tags, such as green fluorescent protein (GFP), to signify expression (Sasmono *et al*., 2003).

Regulated gene expression can also be used to knock out or knock down the expression of endogenous genes in cells and animals. Earlier approaches included antisense or missense DNA, and the most popular method now relies on the introduction of short interfering RNAs (siRNA) and short hairpin RNAs (shRNA) to block transcription of specific genes (Crooke, 2004; Hannon and Rossi, 2004; Wadhwa *et al*., 2004). Together, different transfection modes, coupled with regulated expression plasmids and interfering RNAs, generate a powerful "toolbox" for the investigation and manipulation of gene expression and protein function in mammalian cells. Elements of the toolbox are increasingly adapted for high-throughput analysis of recombinant protein localization and function in whole proteomes.

3. Bypassing genes with protein expression

In addition to recombinant genetic approaches, the introduction of biologically active macromolecules (polypetides, genes, drugs, or other materials) directly into

mammalian cells offers another approach for experimentation and therapeutics. Small cationic, often arginine-rich peptides known as protein transduction domains (PTDs; usually of 9–16 amino acids) can be used to gain entry into cells with macromolecules fused or cross-linked to them. Some of the PTDs in use include those derived from nucleic acid binding proteins such as the human immunodeficiency virus Type 1 TAT protein, the *Drosophila* homeotic transcription protein antennapedia (Antp), and synthetic peptides such as nonaarginine (R(9)) (Becker-Hapak *et al*., 2001; Beerens *et al*., 2003). The exact mechanism by which PTDs actually enter cells is still not completely clear but appears to involve binding of the charged peptides to heparan sulfate residues on cell surfaces, and then either direct membrane penetration, endocytosis, or macropinocytosis in lipid rafts (Beerens *et al*., 2003; Wadia *et al*., 2004). Protein transduction technology is potentially amenable to high-throughput assays and provides exciting possibilities for the future. On the basis of the high efficiency of delivery promised by this method, one might envisage the use of protein transduction technology in high-throughput assays for investigating signaling or enzymatic pathways and for screening the effects of drugs or small molecules on a transduced protein.

4. High-throughput approaches: transfected mammalian cell arrays

Analysis of gene function in mammalian cells traditionally involves the transfection of DNA constructs into cells to overproduce individual protein products and then monitoring its influence on the functions in various cellular processes. Typically, the adaptation of these approaches to screen large numbers of proteins for various cellular phenotypes is not practical. However, recent studies have started to develop the technologies, both transfection and image analysis, required to perform such cell transfection–based screens that go beyond the 96- or 364-well-based format.

Recently, a microarray-based transfection strategy termed reverse transfection or cell microarrays, has been described (Ziauddin and Sabatini, 2001). Using standard microarray robotics, nanoliter quantities of DNA products in an aqueous gelatin solution are printed onto a glass slide that can be stored. After exposure to the transfection reagent, the slides are placed in a culture dish and covered with cell suspensions of adherent mammalian cells. Cells growing on the printed areas take up the DNA, creating regions of localized transfection throughout a lawn of nontransfected cells. This high-throughput adaptation allows thousands of different expression constructs to be expressed in adherent mammalian cells in parallel on an individual glass slide. The effect of each expression construct can be gauged by studying the cluster of living cells present at each spot location. For example, a single spot of 200–500 μm diameter can contain 30–80 transfected cells (Figure 1). Fluorescent products can be detected at low resolution using microarray scanners or at high resolution using microscopy. In addition, methods have been developed to detect radiolabeled products using autoradiography film and the transfer of the cell arrays to nitrocellulose for analysis by western blotting. Further optimization of cell microarray techniques, image capture, and analysis has now been reported (Baghdoyan *et al*., 2004).

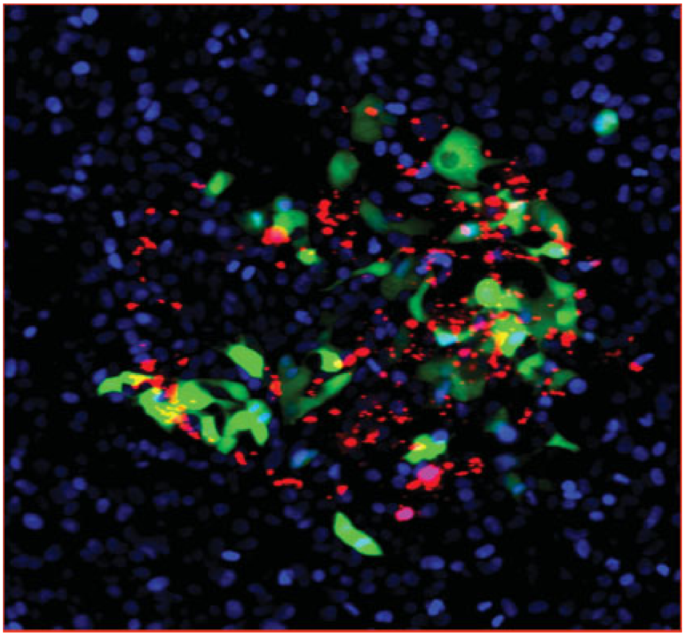

Figure 1 Reverse transfection microarray. This staining demonstrates the transfection technology first developed by the laboratory of David Sabitini (Ziauddin and Sabatini, 2001), and details of their methods are available on the following website (**http://jura.wi.mit.edu/sabatini_public/reverse_transfection/paper_home_page.htm**). This image, produced by A. Forrest, Institute for Molecular Bioscience, University of Queensland, shows a single printed array spot (500 µm in diameter), highlighted using a red Cy3-labeled protein carrier, containing an expression plasmid encoding GFP. Only the cells located over the array spot have been transfected with the plasmid as indicated by the green fluorescence from the expressed GFP. All cell nuclei have been staining with blue fluorescent DNA probe DAPI

To illustrate the utility of cell microarrays, a number of proof-of-principle assays have been established to detect gene products that can induce a range of cellular phenotypes. These assays, in principle, could be scaled to application on a genome-wide scale. Ziauddin and Sabitini (2001) identified gene products that increased the activity of kinase signaling pathways based on a general increase in tyrosine phosphorylation as detected by an anti-phosphotyrosine antibody. A more specific signaling pathway reporter has also been developed on the basis of the transcription reporter assay involving the serum response enhancer (SRE) element coupled to GFP to monitor transcriptional activity modulated by the transfection of individual gene products (Webb *et al*., 2003). A further level of analysis was superimposed in this case by using selective chemical inhibitors to block specific signaling pathways capable of activating SRE.

Protein microarrays that are generated by printing recombinant proteins onto slides at high spatial density have been screened for their ability to interact with proteins and chemical agents (Zhu *et al*., 2001; *see also* Article 24, **Protein arrays**, Volume 5). Similar applications have been developed for cell microarrays, which have the significant benefit of generating the protein and performing the assay

in the context of intact mammalian cells, rather than using purified recombinant individual proteins (Bailey *et al*., 2002). Ziauddin and Sabitini (2001) were able to detect radiolabeled small molecules FK506 and dopamine D1, specifically binding transfected cell arrays expressing their respective receptors FKBP12 and dopamine D1. Cell arrays have been used to analyze the ligand-induced activation of GPCR (Mishina *et al*., 2004). In this work, cell arrays that were prepared expressing 36 GPCRs with a promiscuous Gα subunit were screened for agonist stimulation using a fluorescence-based calcium flux assay. This approach allowed the parallel analysis of GPCRs to rapidly determine receptor specificity for individual agonists and was adaptable to assay the agonist stimulation or antagonist inhibition.

The cell array technology is also suitable for transfection of RNAi probes, either siRNA (Erfle *et al*., 2004; Kumar *et al*., 2003; Mousses *et al*., 2003; Silva *et al*., 2004; Vanhecke and Janitz, 2004) or DNA constructs that direct the expression of shRNA (Silva *et al*., 2004) to assay for knockdown phenotypes in mammalian cells. Using the cell arrays, Silva *et al*. (2004) validated putative positive shRNAs from a previous screen performed in a 96-well format (Paddison *et al*., 2004) for the ability to antagonize the proteosome function using a fluorescent reporter.

A fully automated high-content screening platform capable of automatically acquiring and analyzing high-resolution multicolor images of fluorescent cells has recently been developed (Liebel *et al*., 2003). Both the cell transfection and immunofluorescence labeling in this system were fully automated using liquid handling robotics in a 96-well plate format. While the transfection efficiency was lower (around 30%) than manual transfection, it was sufficient to obtain high-resolution images. Image acquisition required the development of software able to automatically identify the focal plane for each field of view to maximize the capture of "in-focus" images. These images were obtained using a motorized xyz-stage to automatically change samples. Recently, this image acquisition platform has been adapted to live cell arrays (Conrad *et al*., 2004) and further developed to include machine-learning-based image classification methods that allow for the automatic phenotype classification of the acquired images. While these methods were initially used to differentiate image localization (Conrad *et al*., 2004), this machine-learning approach can be readily trained to classify other cellular phenotypes. The further development of these automated high-content screening platforms will greatly expand the repertoire of screens for which the cell arrays can be applied.

5. Location – key information for analyzing expressed proteins

Eukaryotic cells contain a number of distinct, membrane-bound subcompartments or organelles. These organelles function to compartmentalize distinct biochemical pathways and physiological processes. In this context, organelles within the cell include distinct structures such as mitochondria and nuclei, more dynamic and changeable organelles such as recycling endosomes or the trans-Golgi network and the plasma membrane (cell surface) itself, all of which are further subdivided into discrete membrane domains (Johnson *et al*., 2004; Miaczynska and Zerial,

2002; Simons and Vaz, 2004). The cytoplasm forms another cellular compartment that is now recognized to mediate frequent exchange of proteins with the nucleus, endoplasmic reticulum, and other organelles. Determining organelle association or subcellular localization is an essential step in characterizing the possible function of a novel protein or in assessing the expression and function of known recombinant proteins. Methods and approaches for investigating subcellular localization are therefore important to all applications of recombinant technology, from analyzing the expression of individual proteins in cells and organisms through to the analysis of whole proteomes (Simpson *et al*., 2001). The subcellular localization of proteins is often complex and subject to change, in keeping with the growing awareness that many proteins have more than one function in the cell. A protein can be a stable, stationary resident of one organelle, exemplified by glycosyl transferases that are targeted to and function in a specific cisterna of the Golgi complex (Opat *et al*., 2001). Alternatively, proteins can have more than one functional location, an example of which is seen in cell surface receptors that reside initially on the plasma membrane where they function to bind ligand and are then internalized into endosomes from where they generate cell signaling (Gonzalez-Gaitan, 2003). Yet, further complexity arises during protein synthesis and processing during which time newly synthesized proteins pass transiently through the organelles of the secretory pathway, including the endoplasmic reticulum and Golgi complex and a series of carrier vesicles, on their way to their final destination (Lippincott-Schwartz *et al*., 2000). The membrane domain or organelle to which a protein is targeted and then resides is determined by information encoded in its amino acid sequence or by interactions with other proteins or lipids (van Vliet *et al*., 2003).

6. Tagging expressed proteins – the fluorescence revolution

For several decades, antibodies have been used as the main tool for detecting, localizing, and isolating proteins of interest (Myers, 1989). With the advent of recombinant protein expression have come new methods for tagging and visualizing proteins (Fritze and Anderson, 2000). Epitope tags are amino acid sequences that are added to DNA constructs to encode short peptides derived from mammalian proteins, such as the myc epitope, or from synthetic sequences, such as FLAG (Einhauer, 2001; Ellison and Hochstrasser, 1991). In the expressed protein, the epitope tags are then detected using antibodies for localization or isolation of the recombinant protein (Fritze and Anderson, 2000). Tagging recombinant proteins has become another essential component in the "toolbox" for gene and protein expression in individual experiments and in high-throughput systems. The introduction of fluorescent protein tags is surely the most significant advance in this field, revolutionizing our ability to track expressed proteins in fixed and in live eukaryotic cells. Just like antibodies, fluorescent protein tags have been developed for scientific use by exploiting nature itself. The prototypical fluorescent tag is GFP, a bioluminescent protein cloned from *Aequorea victoria* jellyfish with the genetically encoded ability to stably and brightly fluoresce (Chalfie *et al*., 1994). GFP can be expressed in the context of many expression vectors to form chimeras with

a protein of interest, which can then be introduced and expressed in cells or whole organisms. GFP is remarkably inert in eukaryotic cells. Perhaps the biggest bonus in most experimental systems is how little GFP overexpression appears to affect the biology and survival of mammalian cells, whole animals, or plants. Equally valuable is the general finding (with notable exceptions) that chimeric proteins incorporating GFP as a tag retain their ability to correctly fold, be trafficked within the cell, and to function. One of its potential drawbacks of using GFP as a tag is its large size (27 kDa), and of course there are (usually unreported) instances where the addition of GFP does interfere with protein synthesis and or function, and this must be assessed empirically in each case.

The discovery of other bioluminescent proteins such as DsRed (Baird *et al*., 2000) and further diversity in GFP probes arising from natural spectral variants of GFP or those created by specific mutagenesis of GFP (e.g., yellow or cyan fluorescent proteins, YFP and CFP respectively) have driven the development of techniques for sophisticated multiprobe fluorescence imaging and analysis (Labas *et al*., 2002). The simultaneous expression of multiple proteins tagged with distinct variants of GFP is now a common method for examining the colocalization of the expressed proteins or of organelle markers (Figure 2). There are now also many fluorescent probes available as constitutive or regulatable tags for

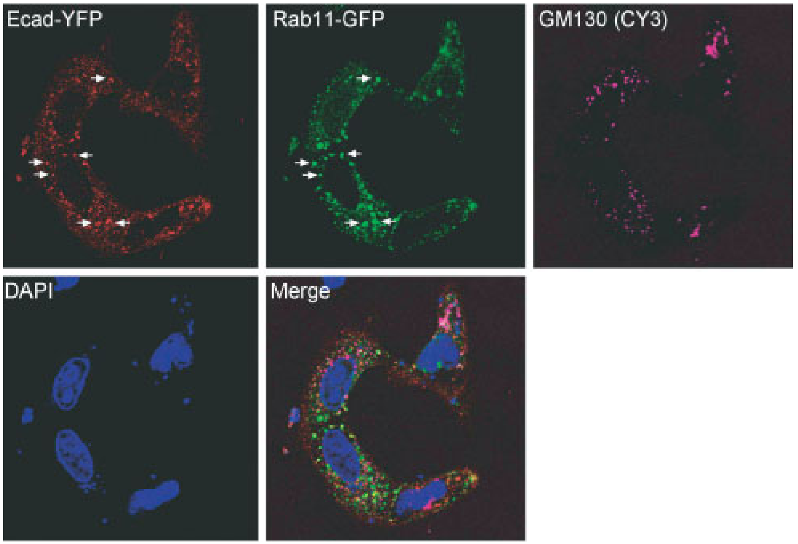

Figure 2 Fluorescence imaging and simultaneous subcellular localization with multiple probes. DNAs encoding two recombinant proteins tagged with different fluorescent tags (green fluorescent protein (GFP) or yellow fluorescent protein (YFP)) have been cotransfected and coexpressed in HeLa cells. After fixation, the cells were immunolabeled to detect a third protein using a CY-3 fluorescent antibody conjugate, and the cells were stained with DAPI to label DNA in the nuclei. Cells were imaged on a Zeiss confocal microscope, and different fluorescent signals were resolved using spectral unmixing. The images show the partial colocalization of a newly synthesized cell surface protein (E-cadherin) that has left the Golgi complex (marked with GM-130) and now transiently resides in recycling endosomes (marked with Rab11) on its way to the cell surface. Images supplied by J. Lock, Institute for Molecular Bioscience, University of Queensland

expressed proteins (Patterson and Lippincott-Schwartz, 2004; Zhang *et al*., 2002). Photoactivatable GFP is one example where, when exposed to bright light at specific wavelengths, the 100-fold increase in the fluorescence emission of this probe allows proteins to be located in a precise and temporal fashion as they move about the cell (Patterson and Lippincott-Schwartz, 2002). The chameleon probes combine multiple, domain-specific GFP variant probes into one gene product to detect calcium based on conformational induced fluorescence resonance energy transfer (FRET) (Miyawaki *et al*., 1997). Taken to an extreme, the multitag, multiexpression strategy will eventually be applied to visualizing complicated protein pathways or complexes under specific physiological conditions.

Techniques such as FRET, which in one form measures fluorescence quenching of a donor fluorophore emission by a closely adjacent acceptor, can be used to study protein–protein interactions in cells expressing CFP- and YFP-tagged proteins, or can be used to study conformational states of a single protein multiply labeled with tags on different domains (Jares-Erijman and Jovin, 2003). Individual events in cell signaling and whole signaling networks are being studied and assembled in cells by FRET analysis (Miyawaki, 2003). The activation state of heterotrimeric G-proteins was resolved in *Dictyostelium* by using FRET labeled with YFP and CFP on opposing G-protein subunits (Janetopoulos *et al*., 2001). The expression of fluorescently labeled proteins and FRET analysis revealed novel locations on the membranes of the endoplasmic reticulum and Golgi complex for critical protein interactions in the Ras signaling pathway (Chiu *et al*., 2002).

In fixed cells, GFP can be detected as a protein tag by virtue of its own fluorescence under UV light, or using antibodies to GFP, which can in turn be detected by standard secondary antibodies in immunofluorescence or by immunogold labeling at an ultrastructural level (Wylie *et al*., 2003). These secondary probes often enhance the detection of small amounts of GFP-expressed protein or enable double labeling with other probes (Gleeson *et al*., 2004).

In live cells, the use of GFP and its variants to tag recombinant proteins has almost single handedly opened up the world of real-time cell imaging (Lippincott-Schwartz *et al*., 2003; Shav-Tal *et al*., 2004). The ability to track individual proteins, carrier vesicles, and compartments in mammalian cells has had a significant impact on the field of protein trafficking. Live imaging of GFP-tagged cargo proteins has provided new insights into the nature of tubulovesicular carriers that perform trafficking, showing information not previously revealed by either light microscopy or electron microscopy (Wylie *et al*., 2003). Intravital imaging of GFP-tagged expressed proteins or other fluorescence markers in live whole animals (Bouvet *et al*., 2002) has now begun to show the real-time behavior of cells during disease processes.

7. Prediction and annotation of subcellular localization of expressed proteins

Analyzing the subcellular localization of individually tagged and expressed proteins is time consuming, and alternative methods for high-throughput or genome-wide

localization studies are only now being developed. To this end, protein localization will increasingly rely on computational methods to predict organellar locations as a prelude to experimental analysis (*see* Article 37, **Signal peptides and protein localization prediction**, Volume 7). Computational methods currently being developed are based on comparison of either the overall amino acid sequence or the sequences of specific domains of proteins with different subcellular localizations. In some cases, the localization of a protein can be attributed to the presence of linear amino acid motifs or sorting signals that actively target proteins to different regions of the cell or to specific organelles. The computational techniques aim to differentiate sets of proteins with known organelle distributions and with this as a base to develop predictions by which to categorize the localization of novel sequences. To date, the most successful methods can differentiate soluble proteins that localize to either the nucleus or cytoplasm, or those that enter the secretory pathway. Other methods have focused on predicting proteins associated with individual organelles including the nucleus (Cokol *et al*., 2000), peroxisome (Emanuelsson *et al*., 2003; Neuberger *et al*., 2003), mitochondrion (Emanuelsson *et al*., 2000; Emanuelsson and von Heijne, 2001; Guda *et al*., 2004), Golgi complex (Wrzeszczynski and Rost, 2004; Yuan and Teasdale, 2002), endoplasmic reticulum (Wrzeszczynski and Rost, 2004), or extracellular space (Chen *et al*., 2003; Grimmond *et al*., 2003). These methods report varying accuracy rates based on their ability to predict the localization of sets of known proteins that frequently overlap with the training sets used in their development, and yet further validation is needed to establish these computational methods for predicting the subcellular localization of novel proteins.

The "components" section of Gene Ontology (GO) terms contains the nomenclature used to describe subcellular localization (*see* Article 82, **The Gene Ontology project**, Volume 8), and then databases such as RefSeq and MGI that incorporate the GO terms can be used as sources to retrieve information regarding protein localization. In addition, Swiss-Prot contains a subcellular localization field (*see* Article 97, **Ensembl and UniProt (Swiss-Prot)**, Volume 8). However, one inherent source of inaccuracy in these databases is that their information on protein localization may be context specific. Many experimental and physiological factors can influence the subcellular localization of an individual protein in temporal and spatial fashions. Some of the compounding factors include:

1. C*ell type*: Different cell types have specialized or unique organelles, for instance, melanosomes in melanocytes or the distinct cell surface domains of polarized cells. Targeting proteins to such organelles or locations often involves unique sorting signals and protein machinery.
2. A*rtifacts of overexpression*: During synthesis and processing, many endogenous proteins form hetero-oligomers that are targeted to a specific organelle by a single constituent subunit. Gross overexpression of a recombinant protein can saturate the biosynthetic and sorting machinery of the cell, disrupting hetero-oligomerization and resulting in aberrant or unrepresentative localization of the foreign gene product.
3. *Overexpressed and tagged proteins*: The location and type of an epitope tag engineered into an open reading frame (ORF) can disrupt the subcellular localization

of the target protein. The addition of protein residues to the amino or carboxyl terminus of a protein can disrupt terminal sorting signals such as mitochondrial transit peptides, endoplasmic reticulum signal peptides, and endoplasmic reticulum sorting signals (Emanuelsson and von Heijne, 2001; Teasdale and Jackson, 1996). Also, although few cases have been documented, the addition of epitope tags can disrupt polypeptide folding resulting in the formation of aggresomes (Johnston *et al*., 1998). The addition of GFP with its relatively large mass (27 kDa) can sterically dominate some small proteins or render them too large for size-dependent sorting events like passage through the nuclear pore. Finally, the epitope tag can dictate subcellular localization in its own right, for example, GFP displays a nuclear and cytoplasmic localization and appears to contain a nuclear localization signal (NLS).

4. *Physiological status of the cell*: The subcellular localization of proteins can change as a direct result of, or incidental to, the stage of cell the cycle or in response to cell signaling events. At present, critical evaluation of these features in experimental approaches is still needed to fully and accurately determine subcellular localization.

8. High-throughput subcellular localization

Experimental approaches and computational approaches for subcellular localization rely on defining a staining pattern for an expressed protein and determining whether this matches one of the characteristic patterns known to represent a particular organelle (Figure 3). Staining patterns for organelles such as the endoplasmic reticulum, the Golgi complex, nuclei, cell surface, and mitochondria are readily recognizable in most mammalian cells, and obtaining one of these patterns for a novel protein gives a first indication as to its likely residence in the cell. Further experimentation or bioinformatics can begin to address some of the caveats to this apparent localization mentioned above; nonetheless, this shot-gun subcellular localization of expressed proteins remains an important information-gathering exercise. Recently, a genome-wide analysis of the subcellular localization of proteins in *Saccharomyces cerevisiae* proteins has been reported (Huh *et al*., 2003). Each of the 6234 annotated ORFs was tagged at the C-terminus with GFP using homologous recombination, and expressed proteins were assessed by fluorescence microscopy combined with colocalization experiments. Seventy-five percent of the yeast proteome was assigned a subcellular localization on the basis of analysis of the micrographs and in selected cases on colocalization with organelle markers. No such extensive study has been performed in mammals, with the majority of protein subcellular localization data being generated by individual groups focused on small sets of proteins. However, recently a number of projects have begun to systematically analyze the subcellular localization of mammalian proteins. First, the European Molecular Biology Labs (EMBL) has established a GFP-cDNA human protein localization project (Simpson *et al*., 2000; **http://gfp-cdna.embl.de/**), which aims to determine the subcellular localization of novel proteins encoded by transcripts generated by the German cDNA consortium (Wiemann *et al*., 2003). It has used the Gateway cloning system (Invitrogen) to

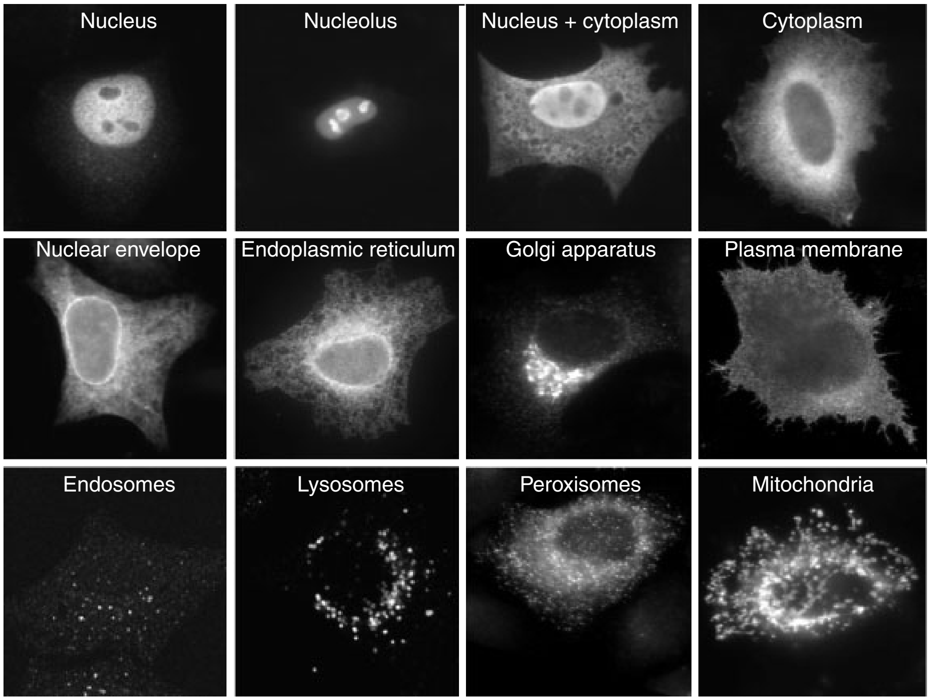

Figure 3 Organelle-staining patterns in cells. Localization of various known and novel expressed proteins in HeLa cells shows a range of diverse staining patterns, many of which are characteristic of subcellular organelles. Images supplied by K. Hanson, M. Kerr and R. Aturaliya, Institute for Molecular Bioscience, University of Queensland

enable rapid generation of N – and C – terminally GFP-tagged human ORFs. To date, over 800 novel human proteins have been analyzed and assigned to subcellular locations. Second, we have initiated a mouse protein localization database (**http://membrane.imb.uq.edu.au/**), which is focused on determining the subcellular localization of sets of membrane proteins predicted using a computational pipeline (Kanapin *et al*., 2003). A megaprimer approach (Suzuki *et al*., 2001) was used to generated expression constructs encoding novel or known membrane proteins with an 11 amino acid myc epitope fused to the N-terminal cytoplasmic domain of each membrane protein, excluding those predicted to contain a N-terminal endoplasmic reticulum signal peptide or sorting signal. To date, over 450 membrane proteins have been experimentally analyzed and assigned a subcellular localization. This experimental data is integrated with the primary literature describing the subcellular localization of membrane proteins into the one resource that currently contains primary subcellular localization data for over 25% of the 4169 predicted mouse membrane proteins.

In the future, the expression and localization of large numbers of proteins in mammalian cells will involve many of the techniques and approaches described herein. A typical approach might entail initial computational screening and sequence-based prediction of protein location, followed by experimental validation of localization and functional analysis of the expressed protein. Such experiments

will require methods incorporating sophisticated fluorescent tagging and efficient gene delivery. Proteins will need to be expressed in multiple cell lines and, perhaps, in animals. Finally, data from these validation experiments will need to be collected using automated microscopy and imaging, and collated and interpreted using intelligent pattern recognition software. The researcher will then have the task of piecing together the many overlapping protein locations, the functional information about expressed proteins and working these into models of mammalian cells in health and disease.

Acknowledgments

We would like to acknowledge colleagues and members of our laboratories, as noted, for providing the data in the figures. Our thanks to Darren Brown for help with preparation of the manuscript. JLS and RDT are each supported by fellowships and grants from the National Health and Medical Research Council of Australia and the Australian Research Council of Australia.

Specialist Review

Integrating genotypic, molecular profiling, and clinical data to elucidate common human diseases

Eric E. Schadt and Alan Sachs
Rosetta Inpharmatics, LLC, Seattle, WA, USA

1. Introduction

One classic approach in widespread use to identify key drivers of complex traits such as common human diseases is the genetic approach proposed by Botstein *et al*. (1980). In this genetic approach, variations in DNA are treated as markers and tested in human and experimental populations for cosegregation with diseases of interest. Markers that cosegregate with a given disease highlight regions in the genome that are considered linked to the disease and that at least partially explain the susceptibility to the disease. Positional cloning strategies and direct testing of positional candidate genes in such regions are then pursued to identify the gene supporting the linkage signal.

This forward genetics approach has proven successful in human and experimental systems for identifying broad regions in the genome associated with disease, and in the case of Mendelian disorders in actually identifying genes underlying such disorders. However, identifying genes harboring common variants that are associated with common human diseases has been less successful, given a number of issues that make such identifications difficult: (1) inadequate sample size, given the frequency of disease or size of the genetic component of disease that can be explained in the population under study; (2) disease heterogeneity (affects ability to initially detect and to replicate); (3) size of regions supported by a given linkage can contain hundreds or even thousands of genes, and narrowing down the region to the gene or genes underlying the linkage is a long and laborious process that is not guaranteed to lead to success; (4) phenotyping inconsistencies resulting in misclassification of individuals into disease groups, which contaminates the signal genetic studies aim to detect; and (5) failure to account for unknown environmental influences or interactions among genes or between genes and environment.

Genetic association studies, in contrast to linkage studies, have increased power to detect genes leading to disease, but these types of studies come with their own set of issues that have prevented broad success. Identifying candidate genes for

consideration in a genetic association test is often highly subjective, driven by biological intuition of what a gene's functional role may be in a disease, rather than more objective data directly implicating the gene's role in disease. Population substructure and admixture may also confound the interpretation of results from these types of studies (Ziv and Burchard, 2003). Further, linkage disequilibrium operating over regions supporting multiple genes containing many variants makes it difficult to identify the gene supporting the association in some cases and the causal variant in the great majority of the cases. Replication is an issue as well given many of the associations detected in one population fail to replicate in other independent populations, and in cases in which replication is achieved the replicated association is often to a different haplotype, complicating the interpretation of the results (Helgadottir, 2004). Even with advances in genotyping technologies and the nearing completion of a human haplotype map that make genome-wide association scans a reality, issues related to the application of appropriate statistical models, multiple testing, and the need to replicate discoveries in such a setting are still problematic. In cases in which associations are detected, it is often the case that the haplotype or causal variants identified as associated with disease suggest no obvious functional role for the associated gene (Helgadottir, 2004; Gretarsdottir, 2003; Pajukanta, 2004; Stefansson, 2002). Finally, genetic studies fail altogether to identify genes central to a complex trait when common variants in such genes simply do not exist in the general population, making detection by genetic linkage or association impossible. Genes such as HMG-CoA reductase regulating important biological processes such as cholesterol synthesis have not yet had common variants identified that associate with traits related to those key biological processes.

Molecular profiling strategies, on the other hand, have the potential to provide much of the needed functional insights into genes and networks more generally found to be associated with disease. The ability to score tens of thousands of phenotypes (e.g., gene expression traits) simultaneously and link those phenotypes to disease traits of interest offers the ability to take an unparalleled look at the molecular processes underlying disease. There has been an explosion of the use of gene expression microarrays and proteomics technologies over the past 5 years toward this end, and a number of novel discoveries have been obtained through the use of this technology, including identification of genes and patterns of expression causally associated with complex disease phentoypes (Karp, 2000; Schadt *et al*., 2003a; Schadt *et al*., 2005), uncovering novel gene structure and alternative splicing events in genes known to be associated with complex disease traits (Johnson, 2003; Schadt, 2004; Shoemaker, 2001), identification of biomarkers (DePrimo, 2003), identification of disease subtypes (Schadt *et al*., 2003a; Mootha, 2003; van 't Veer, 2002), and identification of mechanisms of toxicity (Waring *et al*., 2002).

However, molecular profiling technologies on their own do not provide the information necessary to directly identify key drivers of disease. Technologies such as gene expression microarrays allow for the detection of gene–gene interactions, but do not provide the causal information necessary to infer direction among the many interactions. Others have explored establishing causal relationships among genes by integrating data from multiple sources, including gene expression and proteomic data, single-gene perturbation experiments, and databases of experimentally determined transcription regulatory domains (Lee, 2002; Luscombe,

2004; Sabo, 2004). More recently, the integration of gene expression and genotypic data has been explored as another approach to inferring causal relationships among genes and disease traits. This approach makes use of the naturally occurring DNA variations in human or experimental populations and the perturbations these variations give rise to at the molecular level, and that in turn lead to the complex traits associated with diseases of major public health concern. Jansen and Nap (2001) were among the first to suggest the use of expression profiles in segregating populations toward this end. Studies in *Drosophila* (Jin, 2001; Wayne and McIntyre, 2002), yeast (Brem *et al*., 2002; Yvert, 2003), and mouse (Schadt *et al*., 2003a; Schadt *et al*., 2005; Zhu *et al*., 2004) soon followed, and more recently general surveys on the genetics of gene expression in humans have appeared (Monks, 2004; Morley, 2004).

These recent studies combining genotypic and molecular profiling data to uncover the complex gene networks underlying complex physiological traits related to common human diseases have begun to demonstrate the power that exists in segregating populations to establish causal associations to a wide array of complex traits of interest. In what follows, we review some of these approaches to elucidating common human diseases using integrative genomics approaches where genotypic, molecular profiling, and phenotypic data are combined to refine the definition of a disease trait, identify disease subtypes, make use of the causal information provided by the genotypic data in segregating populations to identify key drivers of disease, and to more generally reconstruct gene networks associated with disease.

2. Experimental setup

While the approach discussed here can be applied to almost any organism, we focus primarily on mouse models for common human diseases. The use of inbred strains of mice to dissect the genetic complexity of common human diseases offers a viable alternative to human studies given that experimental parameters such as environment, breeding scheme, and detailed phenotyping, can be controlled. In addition, mouse models are arguably more relevant to common human diseases than other frequently used experimental systems such as cell lines, yeast, and *Drosophila*. Finally, the mouse models discussed here illustrate the potential power this integrative genomics approach may bring to elucidating the complexity of common human diseases.

The aim of genetic studies in the type of mouse population discussed here is to identify quantitative trait loci (QTL) for molecular profiling and disease traits of interest, and ultimately, to identify the gene or genes underlying these QTL. A standard experimental design employed in these studies consists of crossing two inbred strains of mice that often differ with respect to a phenotype of interest. The two inbred lines of interest are bred and the F1 progeny from this mating are either backcrossed to one of the original inbred lines, giving rise to a backcross (BC) population of mice, or the F1 animals are intercrossed to give rise to an F2 population of mice. While many variations to this type of breeding scheme exist, these types of crosses have been one of the primary workhorses for mouse genetics over the past 30 years. The inbred lines, F1 animals, and BC or F2 animals are then taken

through an experimental protocol that may involve exposure to different environmental assaults, phenotyping with respect to traits of interest, and the BC or F2 animals are genotyped at markers uniformly spaced throughout the genome. In addition, tissues may be extracted and processed for molecular profiling purposes. All of these data taken together form the starting point of the approaches reviewed here.

The integrative genomics approach to dissecting complex traits are highlighted below on a previously described F2 intercross population constructed from the C57BL/6 J and DBA/2 J strains of mice (Schadt *et al*., 2003a; Drake, 2001). In this population, referred to here as the BXD data set, 111 female F2 mice were maintained on a rodent chow diet for up to 12 months of age, and then switched to an atherogenic high-fat, high-cholesterol diet for another 4 months. At 16 months of age, the mice were phenotyped and their livers extracted for gene expression profiling. As described by Drake *et al*. (2001), these mice model the spectrum of disease in a natural population, with many mice developing atherosclerotic lesions, and others having significantly higher fat-pad masses, higher cholesterol levels, and higher bone densities than others in the same population.

The expression studies highlighted for the BXD data set were carried out using oligonucleotide microarrays containing more than 23 000 genes (Schadt *et al*., 2003a; Hughes, 2001). RNA from liver samples of the BXD animals were hybridized against a pool of RNA composed of equal aliquots of RNA from each F2 animal. The gene expression traits treated as quantitative traits in genetic analyses were formed as the log ratio of the intensity measures for each gene represented on the microarray for each sample profiled. While the analyses highlighted in the examples below are focused on these gene expression traits, the general methods described could be applied to any molecular profiling data, including gene expression, proteomics, and metabolomics.

3. Refining the definition of complex diseases and identifying disease subtypes

3.1. A general approach to the identification of disease subtypes

One of the complexities encountered in dissecting common human diseases is the degree of disease heterogeneity represented in almost every population studied. Different pathways associated with different molecular processes may underlie a particular disease, so that any given population represents a mixture of these different subtypes, as depicted in Figure 1(a). Therefore, while individuals may appear phenotypically similar with respect to a physiological trait, the molecular processes that underlie the disease may vary widely from individual to individual. Several studies have highlighted such heterogeneity using microarrays, including a recent study associating patterns of gene expression from breast cancer tumor samples with survival (van ’t Veer, 2002; van de Vijver, 2002). Other studies have demonstrated patterns of expression in different tumor types that allow for disease classification beyond what could be achieved via clinical (e.g., histological) methods (Nutt, 2003; Pomeroy, 2002; Singh, 2002).

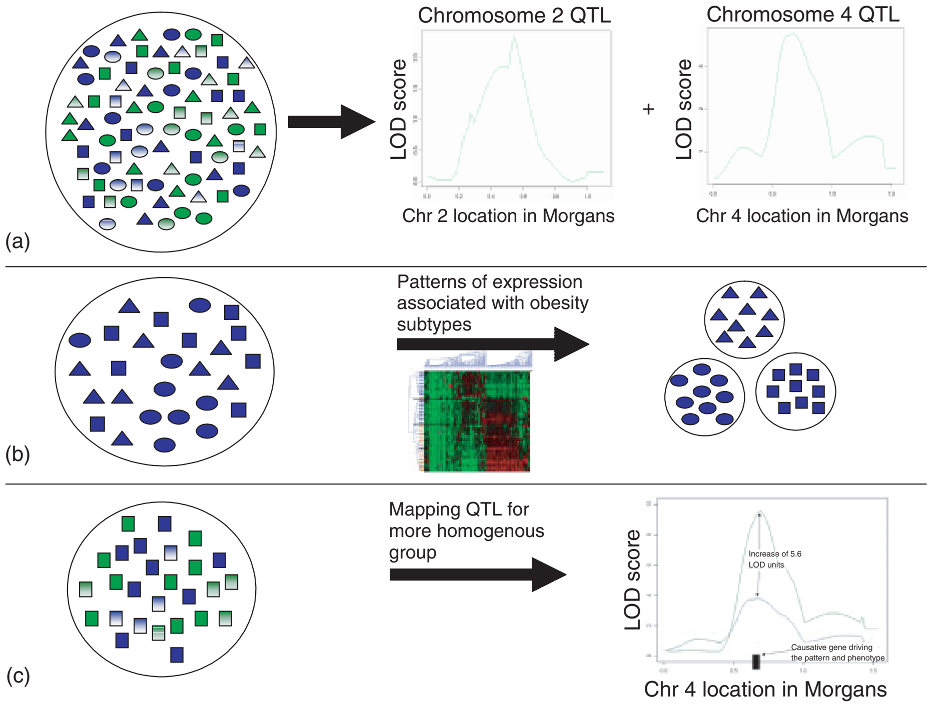

Figure 1 Integrating molecular profiling and genotypic data to refine the definition of disease and identify subtypes of disease. (a) A common scenario in genetic studies is represented here, where the population under study (represented by the large circle) is composed of many families segregating the disease, but with different families potentially segregating different subtypes of the disease. The shapes represent different subtypes of a given disease (here we assume obesity), and the colors represent the extent of disease. In this example, green represents individuals that are lean and blue represents individuals who are obese, with shaded individuals falling somewhere in between. A genetic analysis of this hypothetical population reveals two suggestive linkages to obesity, but neither achieves significance given contamination of the genetic signals by the different subtypes. (b) Expression data from the most obese (or most lean) individuals in the population are examined to identify patterns of expression that are specific to subgroups within the extreme group and that are associated with disease. Therefore, the definition of disease is redefined using the expression data, and the different patterns of expression can result in the identification of disease subtypes. (c) Patterns of expression defining disease subtypes are used to reclassify all individuals in a given population, and then genetic analyses are carried out on these more homogenous subgroups, resulting in a boost to the genetic signal associated with a particular subtype. In this instance, the chromosome 4 linkage here is seen to increase 5.6 LOD units over what was detected when the whole population was considered as a single group (a)

Schadt *et al*. (2003a) demonstrated a novel approach to refining the definition of complex disease states and identifying subtypes by integrating gene expression and genotypic data, providing direct evidence that different subtypes of disease represented in a given population can arise owing to different genetic causes. Figure 1 demonstrates the process used in this study to refine the definition of an obesity phenotype in the BXD data set and then to identify subtypes of the obesity phenotype under the control of distinct genetic loci. Examining a disease trait in a population without knowledge of the different subtypes of the disease represented can lead to significantly reduced power to identify associations to the disease, as depicted in Figure 1(a) and (c). However, if molecular profiling data can

be leveraged to identify more homogenous subgroups, as depicted in Figure 1(b), then performing genetic analyses on these more homogenous subgroups may lead to significantly increased power to identify associations, as shown in Figure 1(c).

3.2. *Application of this approach highlights subtypes of obesity under control of distinct genetic loci*

In the study by Schadt *et al*. (2003a), expression data were used to identify a set of gene expression traits that were able to distinguish the most obese and lean animals. As shown in Figure 2, the set of genes able to discriminate the obese and lean animals gave rise to two distinct patterns of expression in the obese animals, indicating that multiple molecular processes specific to each of the obese groups may explain fat-mass variation in each group. The patterns of gene expression associated with the different high-fat animals refine the definition of the obesity trait beyond what would be possible with the gross clinical characterization of fat mass alone.

To establish whether the different patterns of expression associated with the obesity phenotype were associated with different causes of obesity, Schadt *et al*.

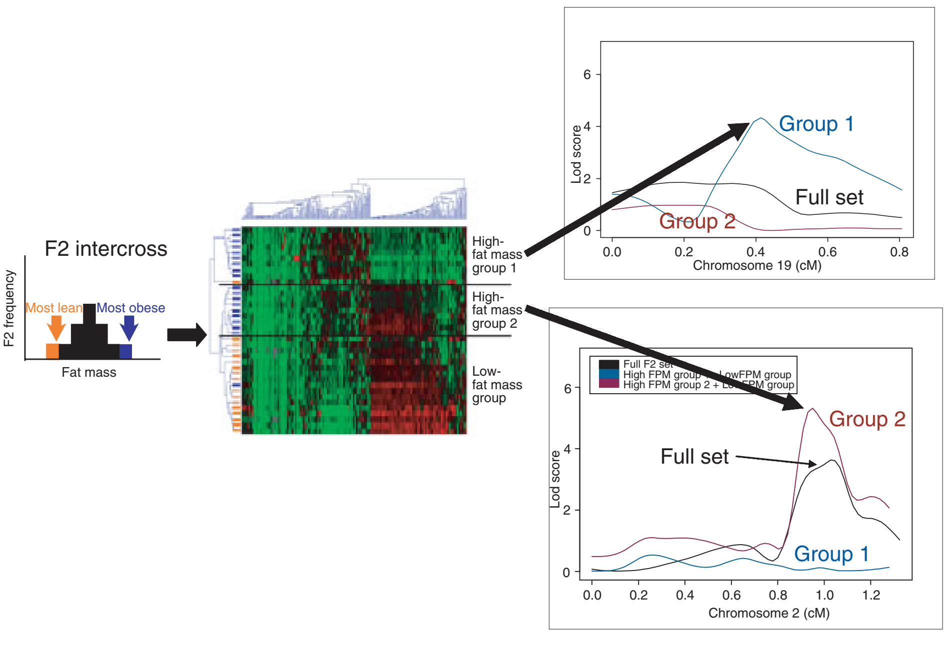

Figure 2 The type of procedure depicted in Figure 1 was applied to identify different subtypes of obesity in a segregating mouse population (Schadt *et al*., 2003a). Extreme lean and obese animals from an F2 population were identified, and expression traits from the most transcriptionally active genes in the liver of these animals were clustered in two dimension using an agglomerative hierarchical clustering procedure. The obese and lean groups clustered together and two distinct patterns of expression were detectable in the obese animals. The two obese groups were seen to represent two different subtypes of obesity, as verified by genetic analysis. The LOD score curves indicate that high-fat group 1 is controlled by a chromosome 19 locus, but not by the chromosome 2 locus, whereas high-fat group 2 is controlled by the chromosome 2 locus but not the chromosome 19 locus

classified all of the F2 animals into one of the three groups defined by the expression data: high-fat group 1, high-fat group 2, or low-fat group. Genetic analysis of each of the two high-fat groups revealed they were driven by distinct genetic loci. As shown in Figure 2, the chromosome 2 QTL completely vanishes when considering mice with expression patterns most similar to that of the high-fat group 1 mice, but increases by almost 2 LOD units over the original LOD score when considering mice most similar to the high-fat group 2 mice. A similar such locus was identified on chromosome 19, where in this case the QTL was specific to animals most similar to high-fat group 1 mice, not high-fat group 2 mice.

This approach provides for subtyping methods that may be less biased than more classic subtyping approaches that seek to identify individuals most informative for a given genetic association. This is because the expression data are an independent source of information used to refine the definition of disease, identify putative subtypes of disease, and ultimately classify the population into the subtypes. In addition, the accuracy of the classifications based on gene expression data can be supported by the simultaneous increases and decreases in linkage strength with respect to the different subtypes. While microarray platforms are subject to a variety of preprocessing issues that can impact interpretation of the data (Miklos and Maleszka, 2004), especially in the classification setting, others have shown that variation in these types of experiments can be controlled (He, 2003), and successes in refining the definition of disease using microarray data have been realized (van 't Veer, 2002; van de Vijver, 2002; Singh, 2002; He, 2003). Still, the application of molecular profiling data in this setting is in its infancy, and further investigations will be required before the utility of the approach can be more generally achieved.

In addition to providing for increased power to detect linkages to disease, refining disease definition using molecular profiling strategies has potentially broad implications for drug discovery as well (Schadt *et al*., 2003b). For instance, because the different subtypes of a given disease may be driven by different, unrelated pathways, different drugs may be needed to target each subtype effectively. In the example described above, developing a drug that targets the gene underlying the chromosome 2 QTL in Figure 2 may only prove effective for the fat group 2 obesity subtype. Identifying that part of the population that stands to benefit the most from such a drug would result in greater efficacy, which not only has the potential to better impact public health, but may also enable greater productivity in the drug development and diagnostic components of the pharmaceutical industry.

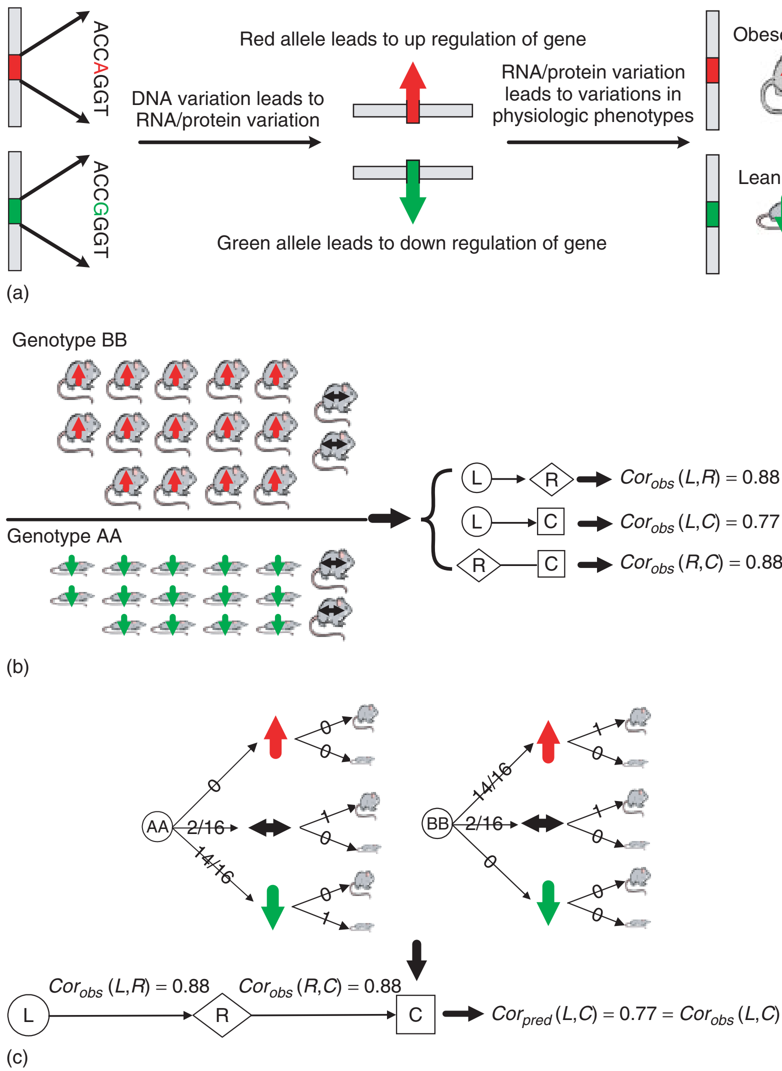
4. Tests for causality to distinguish between causal and reactive RNAs

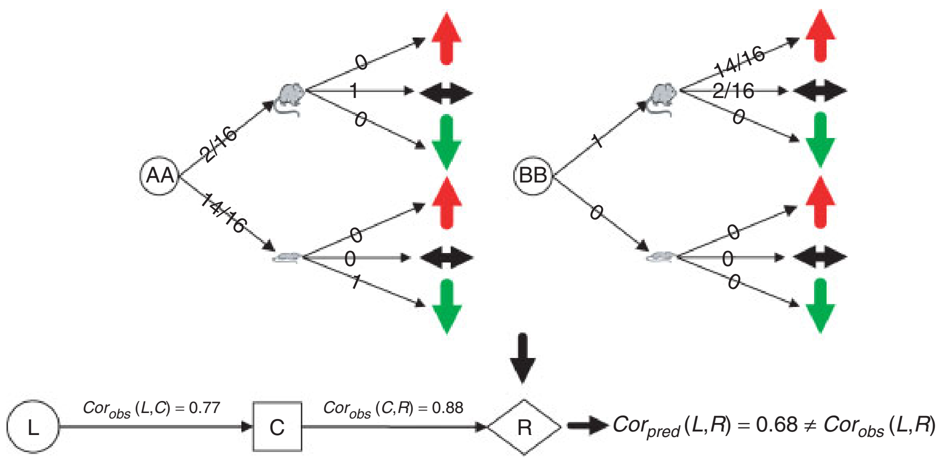
As discussed above, standard molecular profiling experiments are not able to distinguish "causal" events (e.g., RNAs that serve as causative drivers of disease phenotypes) from "reactive" events (e.g., those RNAs whose levels change as a consequence of the disease state) without additional experimentation. This has limited the utility of molecular profiling data (gene expression data in particular) in identifying the key drivers of disease. Several groups have previously spoken

of a strategy of identifying key drivers of complex traits by examining genes located in regions of the genome genetically linked to a complex trait, and then looking for colocalization of cis-acting expression QTL for those genes residing in the region linked to the disease (Schadt *et al*., 2003a,b; Brem *et al*., 2002; Monks, 2004; Morley, 2004). Those genes with (1) expression values that are significantly correlated with the disease trait, (2) transcript abundances controlled by QTL that colocalize with the disease QTL, and (3) physical locations supported by the disease and expression QTL are natural causal candidates for the disease trait. This approach highlights how in segregating populations it is possible to identify variations in DNA sequence that cosegregate with variations in a disease trait, or, more generally, with variations in any complex trait. Whether occurring naturally in a segregating population or induced artificially by methods such as construction of gene knockout in transgenic animals, or gene knockdown using shRNA expression, perturbations such as these allow for the direct study of causal associations between molecular profiling and disease traits, as depicted in Figure 3(a).

To demonstrate how variations in DNA can be associated with variations in molecular profiling traits and disease traits, and how the degree of association can be used to order the molecular profiling traits relative to one another and relative to the disease traits, consider the following simple example. Given that two traits (e.g., an RNA trait and disease phenotype) are driven by the same DNA locus, only three relationships between the two traits are possible, with respect to the DNA locus. Figure 3(c–e) highlight the three possible relationships between a hypothetical expression trait and obesity trait associated with a given locus in a hypothetical mouse population. Figure 3(c) represents the simplest causal RNA model in which the DNA locus (L) controls the variation in the RNA levels of expression (R), which in turn modulates the obesity trait (C). Figure 3(d) depicts the reactive model, in which the DNA locus controls the variation in the obesity trait, which in turn modulates the RNA levels of expression. The independent model is given in Figure 3(e), where the DNA locus independently controls the variation in the obesity trait and RNA levels.

To illustrate how the relationship best supported by the data can be established given gene expression data, or molecular profiling data more generally, and genotypic data in a given population, consider the hypothetical mouse population in Figure 3(b) in which half of the mice have the AA genotype and the other half have the BB genotype at a given locus. As depicted in Figure 3(b), all mice with the BB genotype are obese, while 87.5% of the mice with the AA genotype are lean and the other 12.5% are obese. Further, 87.5% of the BB mice have higher transcript levels with respect to a specific gene, while the other 12.5% have unchanged levels, assuming here that the expression levels for a given mouse are taken relative to the average level over all mice. Similarly, 87.5% of the AA mice have lower transcript levels with respect to the same gene, while the other 12.5% have unchanged transcript levels. To avoid issues of statistical significance surrounding these frequencies, we assume that the hypothetical population is arbitrarily large. In this case, if the obesity and expression trait were uncorrelated with the genotype at locus L (i.e., not significantly linked to this locus), we would expect an equal percentage for each of the expression/obesity trait combinations for each genotype





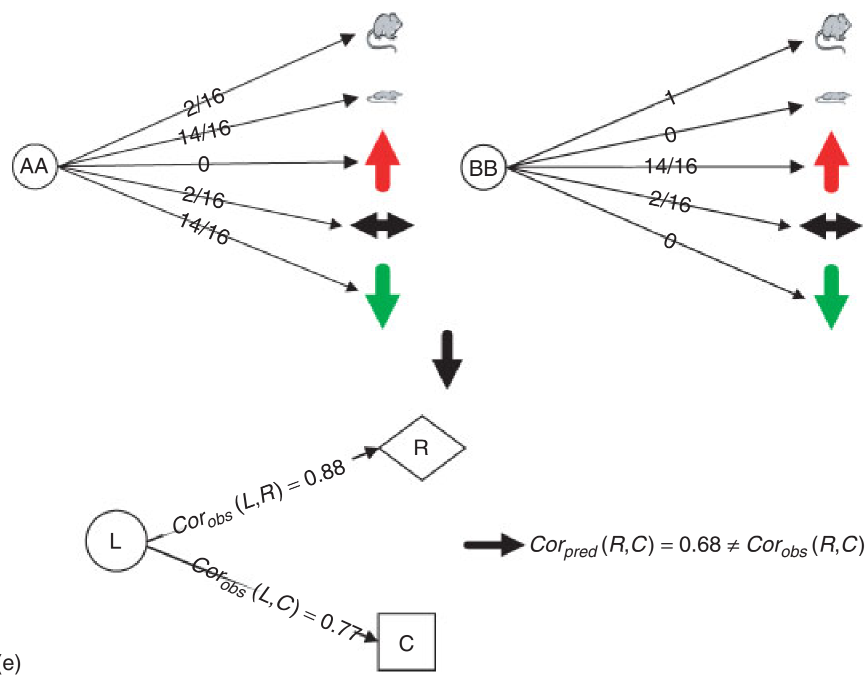


Figure 3 Inferring causality from a hypothetical mouse population. (a) Inferring causality from molecular profiling data follows naturally from the Central Dogma of Biology. Here the red allele ("A") and green allele ("G") are shown to lead to up- and downregulation, respectively, of a gene expression trait associated with the DNA polymorphism. In turn, these changes lead to perturbations in the transcriptional network that in turn lead to obese and lean mice. (b) Obesity is shown to cosegregate with genotypes at a hypothetical locus in a hypothetical mouse population. The expression of a particular gene is also seen to be associated with this same locus, where red, black, and green arrows indicate up-, neutral, and downregulation of the gene, respectively. The structure of the population depicted here allows us to compute the observed correlation coefficients provided to the right of the diagram (Cox and Hinkley, 1974), where L represents the locus associated with the AA and BB genotypes, R represents the transcript abundances of the gene, and C represents the obesity phenotype (either obese or lean). (b, c, d, and e) From the observed correlation structure between the locus, gene expression trait, and obesity trait given in (b), we can assess whether the relationship between the expression trait and the obesity trait is best supported by the model depicted in (c), (d), or (e). For each diagram, the numbers given along the directed edges represent the fraction of animals with the trait value given at the end of the edge, conditional on the trait value at the beginning of the edge. These fractions can be derived from the information in (b) and form the basis of the correlation coefficient calculations. As described in the text, the expression trait as causal for the obesity trait (c) is the relationship best supported by the data

(d)

(e)

Figure 3 (*continued*)

at locus L. Since this is clearly not the case in Figure 3(b), we can conclude that the expression and obesity traits are significantly linked to locus L.

To determine in this example if the RNA is a cause or consequence of the clinical state, the correlation structures between the variables of interest are examined in the context of each of the possible models shown in Figure 3(c–e). Figure 3(c) highlights the causative model, with respect to the RNA trait, where the correlation

between the genotypes and obesity trait predicted from the model is seen to be consistent with the observed correlation. This scenario is equivalent to the situation in which the correlation between the obesity trait and genotype, given the gene expression state, is 0 (i.e., the obesity trait and genotypes are conditionally independent, given the expression trait). Because the obesity trait and genotype are uncorrelated, once we condition on transcript abundances, we can conclude that the RNA is causal for the clinical trait (Pearl, 1983). Figure 3(d) highlights the reactive model, in which the observed correlation between the gene expression trait and genotype is 0.88, but the predicted value is 0.68. Therefore, the correlation between the expression trait and genotype predicted from the model does not equal the observed correlation. In this case, the expression trait and genotypes will still be significantly correlated after we condition on the obesity trait, confirming that the RNA levels are not responding to the obesity trait. Finally, Figure 3(e) highlights the independent model, where again the correlation between the gene expression and obesity traits predicted from the model is not consistent with the observed correlation. Therefore, given the results of the fits to these three models, the data for this hypothetical example indicate that the causative model is the most parsimonious and thus is the best explanation of the underlying biology. We conclude that the AA/BB locus controls variation in the RNA levels and that this RNA, in turn, controls variation in the obesity trait, rather than the RNA levels changing as a consequence of the obesity.

This type of reasoning can be formalized in statistical algorithms and applied systematically to genotypic, molecular profiling, and clinical data to identify causal relationships among molecular profiling traits and between molecular profiling and clinical traits. Schadt *et al*. (2005) develop this approach and apply it to the B × D data set, identifying and validating three novel susceptibility genes for obesity. However, it should be noted that the example described above was simplified in order to describe how causal information can be derived from the genotypic and molecular profiling data. In practice, there are a number of issues to consider before such an approach can be carried out. One such issue is the dependency of the identification of the correct relationship among traits on measurement and modeling errors. Suppose RNA trait R is actually causal for trait C, but the measurement errors related to the expression of R far exceed that of C. This may lead to a failure to detect R as causal for C, or worse, would incorrectly identify C as causal for R. Therefore, it is important that measurement errors be appropriately controlled for, either through repeated measures, employing a more accurate means of measuring, or more precisely modeling the error in the likelihood equations. There are issues in the model selection procedure as well in determining the relationship among traits driven by a common locus. For example, two traits driven independently by a given locus may not be conditionally independent given the locus genotypes. Therefore, it is important to model hidden variables that allow for correlation between two traits that is independent of the given locus. Finally, the high-dimensional nature of this problem in which tens of thousands of molecular profiling traits are considered simultaneously gives rise to serious multiple testing issues. These types of statistical issues are complex, and have only recently begun to be systematically addressed in the published literature.

5. Elucidating genetic networks underlying disease

The ability to infer causal associations among traits of interest can be more generally applied to one of the most pressing problems in complex disease research: the reconstruction of gene networks associated with disease. In order to make connections between the large sets of genes screened in molecular profiling experiments and disease traits, it is now commonplace to map genes screened in such experiments to known pathways or other annotation sets that can then be tested for enrichment compared to a more complete reference gene set (Mootha, 2003; Lenburg, 2003; Wu, 2002). Forming relationships between different traits as discussed above can be more generally modeled using graphical structures constructed from the experimental data. Such models allow for the efficient identification and representation of relationships among genes and between genes and disease traits. As discussed above, causal inferences can be derived from molecular profiling and disease trait data via QTL data, thereby providing a novel source of information that complement gene expression data and that can be incorporated into methods that seek to identify graphical models (gene networks) of gene interactions.

In order to systematically study complex gene networks in living systems, genes have to be systematically perturbed and the responses to such perturbations recorded. Common systematic perturbation methods include knocking in/out genes, inhibiting gene activity using chemical compounds (e.g., drugs), inhibiting/activating a gene's expression using RNAi technologies (e.g., siRNA, shRNA), and constructing transgenics. Many of these techniques are time consuming and may lack the multifactorial context needed to achieve complex phenotypes of interest, given that many complex phenotypes are the result of multiple genes interacting in complex ways with different genetic backgrounds and environmental conditions, as depicted in Figure 4. Other techniques such as chemical and siRNA inhibition can be accomplished efficiently, but these techniques frequently give rise to off-target effects that cannot be resolved in the absence of additional experimentation (Jackson, 2003), and they cannot always be carried out in the appropriate biological context. For example, typically such experiments need to be carried out using cell-based assays instead of living animals being exposed to the environmental conditions giving rise to the clinical phenotypes of interest.

Naturally occurring genetic variations have the potential to address many of these shortcomings. This type of perturbation has yet to be fully exploited on a genome-wide scale using gene expression or other molecular profiling data, despite it being one of the more comprehensive forms of multifactorial perturbations available in mammalian systems. Zhu *et al*. (2004) recently extended the classic Bayesian network reconstruction methods to incorporate QTL information for the transcript abundances of each gene expression trait considered in a set of experiments of interest. Networks in this setting are composed of nodes, representing genes, and directed edges, representing causal interactions between two genes, as depicted in Figure 5. The causal information used to direct edges in such a network obtain from the genetic information described above. That is, if RNA levels for two genes are genetically controlled by a similar set of genetic loci, then their expression QTL should overlap. In a previously described work (Zhu *et al*., 2004), the extent of QTL overlap was measured by computing the correlation coefficient between vectors of

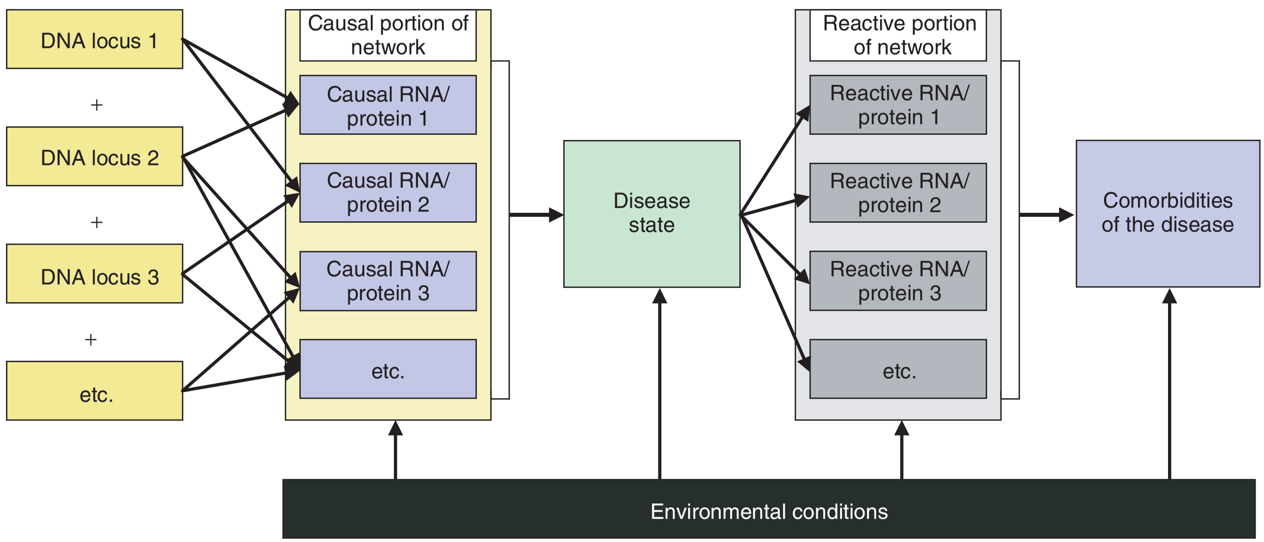

Figure 4 A simple diagram of the molecular causal and reactive events associated with common human diseases such as obesity. The DNA loci represent variations in DNA that in turn lead to changes in RNA or protein. These changes give rise to a larger perturbation in the genetic network that ultimately leads to a given disease. The disease state can in turn cause other changes in the genetic network that lead to comorbidities of the disease (e.g., obesity can increase risk for other diseases such as diabetes and heart disease). In addition to the genetic causes of disease, environmental factors also play a critical role, as common human diseases are the result of complex interactions among multiple genetic loci and between the genetic loci and environmental factors

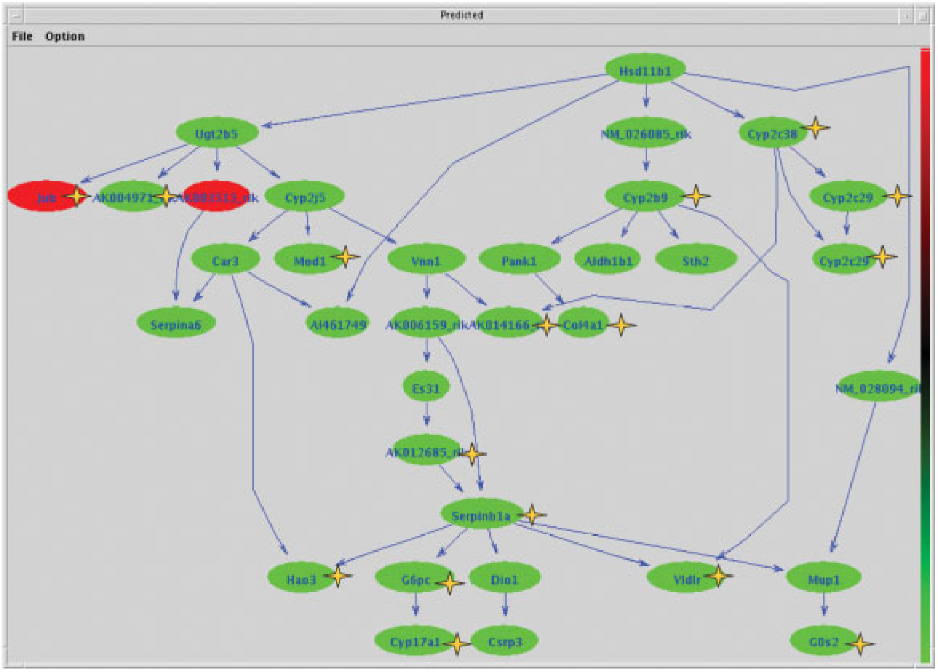

Figure 5 A previously reported (Zhu *et al*., 2004) predicted subnetwork from the liver expression data of the BXD cross described in the text. The subnetwork is centered at the gene HSD11B1 node. The nodes (genes) making up this subnetwork were identified from the larger liver gene network constructed from the BXD data set, by constraining to those nodes having a path to HSD11B1 no longer than three links. Pictured here are the 33 gene nodes meeting this criteria. The stars indicate the 20 genes represented in the Ppara signature previously described (Zhu *et al*., 2004). The gene expression state of each node is colored according to the predicted state when HSD11B1 is in the downregulated state. Red indicates a gene is upregulated relative to the reference pool, green indicates a gene is downregulated relative to the reference pool, and no fill indicates a gene is not differentially expressed relative to the reference pool

LOD scores associated with eQTL identified over entire chromosomes for each gene.

Employing this type of technique to the BXD data set described above, Zhu *et al*. demonstrated that the genetic information allowed for a more predictive network than could be realized using standard, state-of-the-art Bayesian network reconstruction methods, when validated against an independent, single-gene perturbation experiment. The network depicted in Figure 5 from this study gave rise to significant predictive capabilities in that 20 of the 33 genes predicted to change in response to perturbing HSD11B1 indirectly were identified as significantly changed in response to specific drug target experiments in which HSD11B1 activity was perturbed. In this experiment, perturbing HSD11B1 was achieved by activating the peroxisome proliferators activated receptor alpha (Ppara) gene. Only 10 genes would have been expected by chance (the *p*-value for enrichment reported by Zhu *et al*. was as 1.7×10^{-4}). When Zhu *et al*. applied the standard state-of-the-art Bayesian methods to these same data, but without making use of the QTL data, the resulting network predicted only five genes to change in response to downregulating HSD11B1. Only 1 of the 5 genes was detected as significantly

changed in the independent drug target experiment, and given 1 to 2 would have been expected by chance, these results were completely insignificant. That is, the QTL information was necessary to achieve significant predictive capabilities.

The causality arguments given above and in Figure 3 could also be incorporated into the Bayesian network reconstruction methods by altering the conditional mutual information measure that is standard in Bayesian reconstruction methods. The mutual information measure central to Bayesian reconstruction methods could be applied to conditional probabilities that take into account genotypic, molecular profiling, and clinical trait data. While the mutual information measure is useful in more general network reconstruction problems, the advance described here is potentially more powerful given the causal anchoring the QTL data provide, and therefore may potentially lead to a more robust and more powerful test for establishing the relationship between any two traits.

There are numerous advantages gained from the reliable reconstruction of gene networks. Novel genes can be placed in the context of known genes, novel pathways associated with disease traits of interest can be identified, interactions among known pathways and between known and unknown pathways can be characterized, and hypotheses generated to further elucidate disease traits and living organisms more generally. However, beyond these basic life sciences applications there is broad utility in the pharmaceutical setting as well. The networks and causal associations between genes and disease traits will result in the identification of targets for therapeutic intervention. For example, genes such as HMG-CoA reductase that do not have common DNA variations associated with, say, cholesterol levels, could be identified in the broader network as they respond to other genes that do harbor such variations and that in turn cause differential regulation in them. Further, in the network context, the potential exists to prioritize targets on the basis of their association with multiple disease traits, so that targets showing not only causal association with diseases such as obesity, but with diabetes and heart disease as well, can be considered in this more comprehensive light.

6. Conclusion

Classic genetic approaches to dissecting common human diseases have sought to push the limits in applying statistical methods to extract the most information from the association of DNA variations and complex trait variation in human populations and model organism systems. However, in the absence of a broader range of phenotypes, the classic genetic approaches have not fully lived up to their potential in identifying the key drivers of common human diseases. Here we have reviewed a novel approach to the dissection of complex traits that involves the integration of genotypic, molecular profiling, and clinical data. The large-scale molecular phenotyping data is used in this process to identify sets of genes associating with and even defining the molecular processes underlying complex disease traits, and ultimately identifying the key drivers of those processes by associating variation in the molecular profiling and disease traits with variations in DNA.

The types of procedures detailed here begin to form the basis for expanding our understanding of pathways associated with common human diseases and complex systems more generally. The networks that can be reconstructed from the types of procedures reviewed here can themselves serve as a source of annotations for future experiments, given they begin to elucidate the actual pathways underlying complex traits. This work represents only the beginning in an exciting new area of biology where integration of data and the reconstruction of pathways and mapping these pathways to meaningful annotations can, in turn, elucidate the functional roles a given pathway may play in living systems. This type of approach offers a promising avenue of biological research to elucidate the complexity of living systems, given the ability to identify the key drivers of complex traits, order genes into pathways associated with these complex traits, and more completely annotate the functional roles genes underlying the complex traits may play.

Of course, these types of methods are not without problems, and they have limitations that should be recognized and taken into consideration. For example, the network reconstruction procedure discussed above does not model feedback control, a control mechanism that is well known to occur in living systems. Many other methods could be explored for these purposes, including ordinary differential equations, dynamic differential equations, and structural equation models, to name just a few. Further, there are many statistical issues to consider in assessing the significance of the networks resulting from methods that integrate genetic and expression data, including how accurately the topologies of such networks reflect the connectivity of the true underlying pathway and confidence measures for the causal associations identified between any two genes. There are other issues to discuss as well, such as the relevance of gene networks over a diversity of tissues to a particular disease state, and how network connections between tissues will vary as networks spanning multiple tissues are constructed. Recent papers have suggested that significant topological changes in gene networks may obtain in response to changing environmental conditions (Luscombe, 2004), which, if true in mammalian systems, would significantly increase the complexity of the network reconstruction problem. However, even in cases in which the actual recovery of the whole network is impossible, it may be possible using the types of techniques described in Figure 3 to partition the network with respect to a given disease trait into causal, reactive, and independent pieces, as depicted in Figure 6. While this would leave one some distance from actual goal of reconstructing whole networks, it may allow molecular profiling data to be partitioned into causal and reactive sets, thereby facilitating more rapid identification of the key drivers of disease.

However, these problems notwithstanding and the additional investigations needed to enhance confidence in causal inferences made from the integration of genotypic and molecular profiling data, the progressive methods discussed here offer new ways to tackle some of the most pressing problems in the biomedical and life sciences research. The integration of large-scale phenotypic data with genome-wide genotypic data provide the ingredients necessary to inform more fully the molecular processes underlying complex diseases. These techniques have the potential to significantly impact the drug discovery process by increasing the probability of success for identifying targets, minimizing costs of clinical trials by targeting the appropriate disease subtypes, and providing patients with drugs

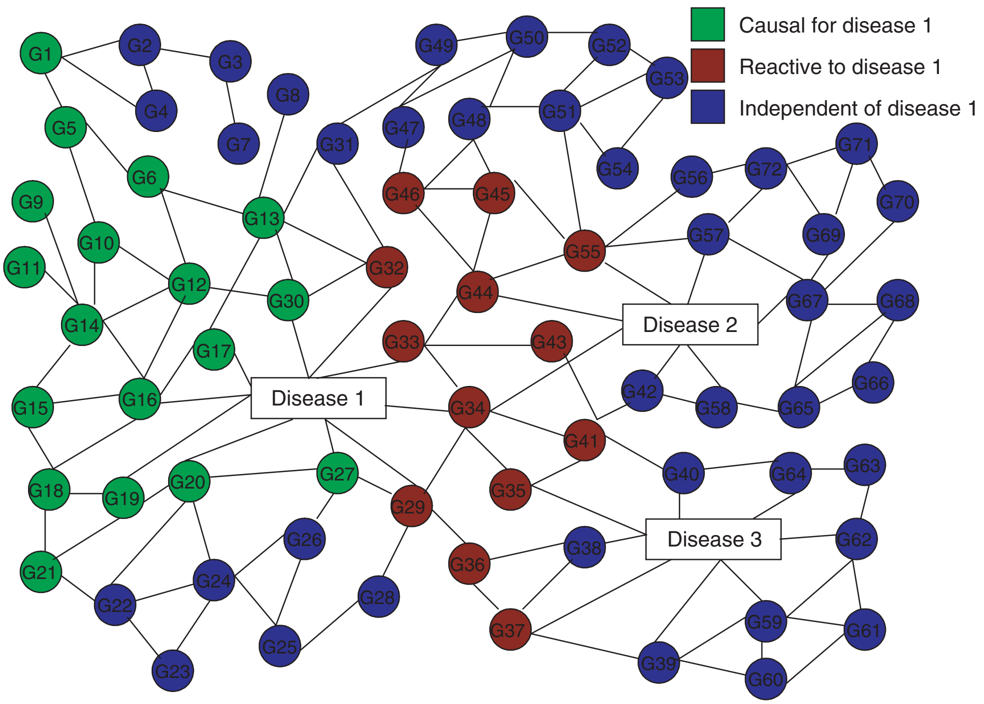

Figure 6 A hypothetical disease-specific genetic network. This simplified view of a genetic network highlights the complex interactions among genes that are associated with common human diseases. While reconstruction of the actual network underlying complex disease traits is still a difficult, if not impossible, problem, partitioning the network with respect to a given disease is possible. Here we illustrate how the nodes in a genetic network can be identified as causal, reactive, or independent of a given disease trait using the type of approach highlighted in Figure 3

that are highly effective for specific diseases that today are only loosely or even incorrectly grouped according to gross clinical symptoms such as obesity.

Specialist Review

The promise of gene signatures in cancer diagnosis and prognosis

Jimmy C. Sung, Alice Y. Lee and Timothy J. Yeatman
The H. Lee Moffitt Cancer Center and Research Institute at the University of South Florida, Tampa, FL, USA

1. Introduction

Precise tumor diagnosis is the first step in cancer management since therapy generally stems from the initial tumor classification (*see* Article 65, **Complexity of cancer as a genetic disease**, Volume 2). While many tumor biopsies are diagnostic and form the cornerstone of cancer therapy, classification of tumor type and site of origin is a significant clinical challenge that is often underestimated. In fact, up to 10% of all metastatic tumors have no definable primary site of origin (Blaszyk *et al*., 2003). The current standard of pathologic practice, using morphologic criteria and *semiquantitative* immunohistochemical (IHC) analyses, is often limited in its capacity to define tumor type or site of origin. Tumors with seemingly identical pathology under the microscope may follow different disease trajectories because of underlying molecular heterogeneity (Golub *et al*., 1999). This diagnostic imprecision, on the whole, may adversely affect the quality of patient care while unnecessarily increasing health care expenditure. Moreover, our inability to predict the future biological behavior of tumors is problematic, leading to the overtreatment of many patients to help an unknown few.

With the mapping of the human genome (*see* Article 24, **The Human Genome Project**, Volume 3), DNA microarray technology, coupled with large-scale methods of gene-expression analysis, has the power to revolutionize cancer diagnosis and treatment. By studying the activity of many genes simultaneously – an approach known as *molecular profiling* (Liotta and Petricoin, 2000) – a genetic portrait of an individual cancer can be generated, providing investigators with greater insight into the cancer's etiology, its responsiveness to therapy, its potential to metastasize, and the probability of patient survival. Molecular profiling holds promise to overcome the limitations of traditional cancer diagnosis with the potential for more accurate cancer classification, improved treatment stratification, and the discovery of new therapeutic targets (Alizadeh *et al*., 2000).

1.1. Molecular signatures for cancer diagnosis

A major challenge of cancer research has been to direct specific treatments to distinct tumor types so that efficacy is maximized while toxicity is minimized (Golub

et al., 1999). Thus, advances in cancer classification are critical to advancing the quality of care available to cancer patients. Historically, classification has relied on subjective interpretations of the morphological appearance of the tumor. Molecular profiling using microarray technology (*see* Article 90, **Microarrays: an overview**, Volume 4) has great potential as a systematic and unbiased approach for assigning particular tumor samples to previously defined classes, as well as discovering new tumor subtypes. Golub *et al*. (1999) were among the first to demonstrate that patterns in gene-expression data could be used to distinguish among different tumor types. On the basis of gene-expression profiling alone, it was possible to distinguish tumor samples of acute myeloid leukemia (AML) from acute lymphoblastic leukemia (ALL). A gene predictor derived from an analysis of microarray data using 38 known acute leukemia samples was capable of accurately classifying 29 of 34 new independent leukemia samples. The gene-expression signature used to distinguish AML from ALL included genes encoding for cell surface proteins (CD11c, CD33, MB-1), those involved in cell cycle progression (Cyclin D3, Op18, MCM3), and known oncogenes (c-MYB, E2A, HOXA9). Next, turning to the question of class discovery, a technique based on self-organizing maps that automatically discovered the distinction between AML and ALL, as well as the distinction between B-cell and T-cell ALL was used. Gene-expression monitoring was shown to provide new and important insights into tumor pathogenesis, as well as future clinical outcome.

Using 218 samples spanning 14 common cancer types, Ramaswamy *et al*. (2001) constructed a classifier based on a support vector machine algorithm. Overall classification accuracy was 78%, exceeding the accuracy of random classification (9%), suggesting the feasibility of cancer diagnosis across the common malignancies based on a comprehensive catalog of gene-expression profiles. This initial work was then extended by Bloom *et al*. (2004) who demonstrated that large public datasets could be combined, normalized, and scaled to produce a multitumor classifier capable of discriminating 21 different tumor types with high degrees of diagnostic accuracy. To accomplish this, sizable gene sets ($n > 500$) were used in combination with a neural network approach to weight the genes in the classifier (Bloom *et al*., 2004). Figure 1 demonstrates the large number of discriminating genes that can be identified in each defined tumor type and subsequently exploited to develop a multitumor classifier.

1.2. Gene signatures for prognosis of lymphoma

The correlation between gene-expression patterns and clinical outcome was first demonstrated by Alizadeh *et al*. (2000) in a cDNA microarray-based study of diffuse large B-cell lymphoma (DLBCL), the most common subtype of non-Hodgkin's lymphoma. Forty percent of patients responded favorably to standard therapy achieving a durable remission, while the remainder succumbed to the disease. This variability in clinical outcome was shown to reflect molecular heterogeneity within the tumors. Hierarchical clustering identified two molecularly distinct types of DLBCL with gene-expression patterns indicative of different stages of B-cell differentiation: one type had a gene-expression pattern characteristic of germinal center B cells, while the second type expressed genes normally induced

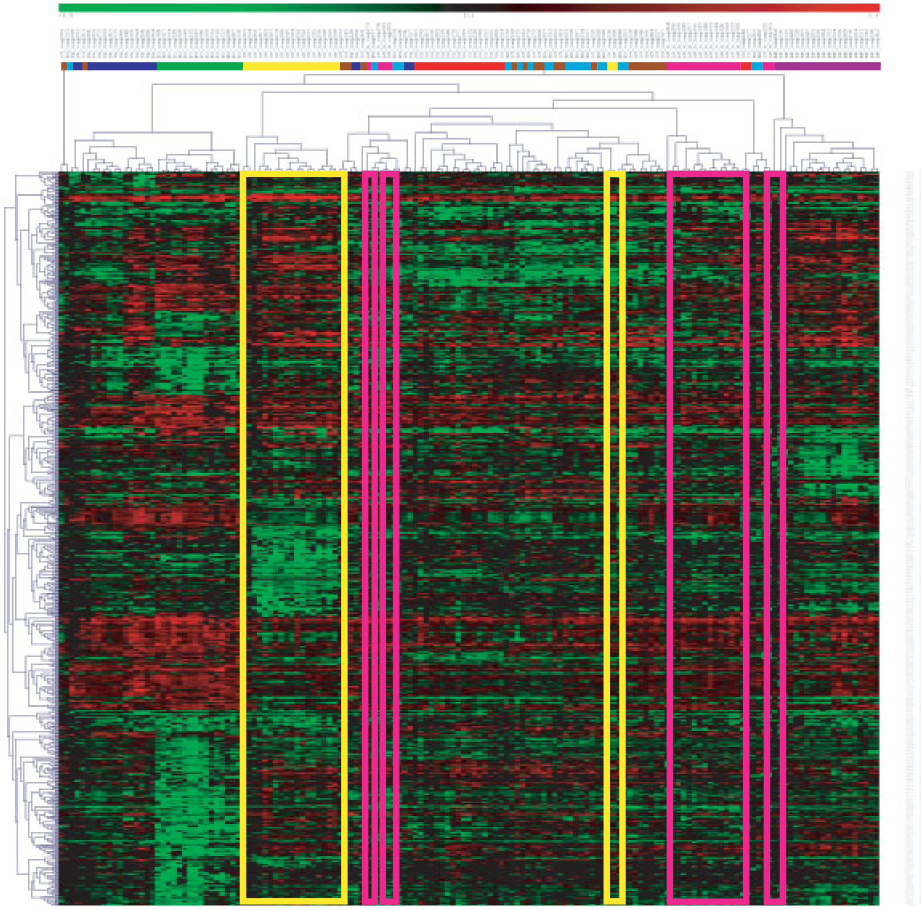

Figure 1 Hierarchical clustering of eight different types of adenocarcinomas. The Kruskal–Walls H-test was used to identify those genes most correlated with each tumor type, selecting ∼700 genes from 30 849 distinct transcripts on the cDNA chip. Average linkage hierarchical clustering of spotted cDNA array expression data using a Pearson correlation coefficient distance matrix illustrates the problems with this approach to classification, which typically weights each gene equally. Even for ovartan cancer samples (yellow boxes), which are generally well classified, there are two cutlying samples that are grouped within a set of diverse tumors. For other tissues of origin such as lung (pink boxes), the situation is worse. Similar results are obtained for samples assayed using Affymetrix GeneChips. Although hierarchical clustering can be used with weights for each gene, we have no a priori means of determining the appropriate weights. This is the rationale that underlies the use of the ANN in tumor classification. (Reproduced with permission from Bloom *et al*. (2004) Multi-platform, multi-site, microarray-based human tumor classification. *American Journal of Pathology*, **164**(1), 9–16. © The American Society for Investigative Pathology)

during in vitro activation of peripheral blood B cells. Patients with the germinal center B-like DLBCL showed a significantly higher posttreatment survival rate (76% versus 16%) than patients with the peripheral blood B type, demonstrating that gene expression-based tumor classification can identify clinically significant subtypes of cancer. In fact, the clinical divergence between the two types was so remarkable that it was suggested that the two subtypes be regarded as distinct diseases. Alizadeh *et al*. (2000) anticipated that such large-scale microarray data

analyses would identify a small group of marker genes that can be used to stratify patients into molecularly distinct categories, thus improving the power and precision of clinical therapies. For example, by determining which patients are unlikely to respond to standard chemotherapy, more aggressive therapies, such as bone marrow transplantation, could be recommended early on. Additionally, as the two classes of DLBCL differentially expressed entire transcriptional modules consisting of hundreds of genes, new drugs might be developed to target the upstream signal-transducing molecules that are responsible for the expression of pathological transcriptional programs.

More recently, Dave *et al*. (2004) used gene-expression profiling to construct a molecular predictor of survival length for the second most common form of non-Hodgkin's lymphoma – follicular lymphoma. The gene-expression signatures used to construct the survival predictor, which included genes that encode T-cell markers (e.g., CD7 and STAT4) and genes highly expressed in macrophages (e.g., ACTN1 and TNFSF13B), allowed patients to be divided into four quartiles with widely disparate median lengths of survival (ranging from 13.6 to 3.9 years), independently of any clinical prognostic variables. Surprisingly, these signatures were derived from nonmalignant cells in the tumors, revealing the important role of the host immune system in the development of this type of malignancy and pointing the way to possible new targets for therapy.

1.3. Gene signatures for prognosis of solid malignancies

Not only has molecular profiling revealed subtypes and expression signatures that could improve prognostic classification in blood cancers (leukemia and lymphoma), but high-throughput gene profiling has shown great promise in the study and treatment of solid tumors as well. Using cluster analysis on cDNA microarray data representing 8201 genes, Perou *et al*. (2000) characterized variation in gene-expression patterns in set of 65 specimens of breast tumors from 42 different patients. These gene-expression patterns provided a distinctive molecular portrait of each tumor, with patterns in two samples from the same individual almost always being more similar to each other than either was to any other sample. Moreover, variations in growth rate, in the activity of certain signaling pathways, and in the cellular composition of the tumors, were all reflected in the corresponding variation in the expression of specific subsets of genes. For example, the expression of a large cluster of genes regulated by the interferon pathway (including STAT1) varied widely among the tumor samples. Dendogram diagramming also divided the samples into two major subdivisions – an estrogen-receptor positive group, characterized by the relatively high expression of many genes expressed by breast luminal cells, and an estrogen-receptor negative group. It was discovered that the estrogen-positive group could be further subdivided into two groups, each with a distinctive expression profile and significantly different survival outcomes (Sorlie *et al*., 2001). Interestingly, Perou *et al*. (2000) discovered that a metastasis and primary tumor were as similar in their overall pattern of gene expression as were repeated samplings of the same primary tumor, suggesting that the molecular program of a primary tumor may generally be retained in its metastases.

Further, gene expression–based research into the clinical behavior of breast cancer was performed by van't Veer *et al*. (2002). Using supervised clustering on microarray data taken from 117 breast cancer patients, van't Veer *et al*. identified a gene-expression signature predictive of a short interval to distant metastases ("poor prognosis" signature) in patients without tumor cells in local lymph nodes at diagnosis. A prognosis classifier consisting of 70 genes predicted to 83% accuracy the actual outcome of disease. Genes significantly overexpressed in the poor prognosis signature included those involved in cell cycle, invasion and metastasis, angiogenesis, and signal transduction (e.g., cyclin E2, MCM6, MMp9, PK428, and the VEGF receptor FLT1) and represented potential targets for the rational development of new cancer drugs. This gene-expression profile outperformed all currently used clinical parameters in predicting disease outcome, thus providing an improved strategy for selecting patients who would benefit from adjuvant therapy.

Bhattacharjee *et al*. (2001) have proposed a gene expression-based taxonomy of lung cancer, the leading cause of cancer death worldwide. Using oligonucleotide microarrays (*see* Article 92, **Using oligonucleotide arrays**, Volume 4), mRNA expression levels in 186 lung tumor samples were analyzed, including 139 adenocarcinomas resected from the lung. Hierarchical and probabilistic clustering of expression data defined distinct subclasses of lung adenocarcinoma, including one cluster most likely representing metastatic adenocarcinomas from the colon. One subclass, characterized by several neuroendocrine markers such as dopa decarboxylase and achaete-scute homolog1, showed a significantly less favorable survival outcome than all the other groups. Another subclass, characterized by the highest expression of type II alveolar pneumocyte markers, was associated with a more favorable clinical outcome. Interestingly, two adenocarcinoma subclasses were associated with lower tobacco-smoking histories. More recently, Tomida *et al*. (2004) created a prediction classifier based on the expression profiling of 50 patients with non-small-cell lung cancer, which comprise 80–85% of all lung cancers. The resultant classifier yielded 82% accuracy for forecasting survival or death 5 years after surgery. Furthermore, unsupervised hierarchical clustering analysis revealed for the first time the existence of clinicopathologically relevant subclasses of squamous cell carcinomas with marked differences in invasive growth and prognosis. Overall, the discovery of such distinct subtypes of lung carcinomas suggests that the integration of gene-expression profile data with clinical parameters could significantly aid in the effective diagnosis and individualized treatment of lung cancer patients.

A previously unrecognized taxonomy based on molecular profiling has also been proposed by Bittner *et al*. (2000) for the most common human cancer – melanoma. Currently, no well-established histopathological, molecular, or immunohistochemical marker defines subclasses of this neoplasm. Through cluster analysis, a distinct subset of melanomas was discovered whose characteristic genes were differentially regulated in invasive melanomas that form primitive tubular networks in vitro, a feature of some of the most highly aggressive melanomas. Notably, no statistically significant association was found between the cluster groups and any clinical or histological variable, such as age, sex, biopsy site, or in vitro pigmentation. In their analysis, Bittner *et al*. generated a ranked list of individual genes (e.g., WNT5A,

MART-1, pirin, HDHB) with the most power to define the clusters of the 19 samples studied, providing a sound molecular basis for the dissection of other clinically relevant melanoma subtypes and for greater understanding of the more aggressive forms of this cancer.

Another study (Ramaswamy *et al*., 2003) using expression profiling has challenged the prevailing model of metastasis, which holds that most primary tumor cells have low metastatic potential, while rare cells (less than 1 in 10 million) within primary tumors acquire metastatic capacity through mutation. A gene-expression signature was discovered that distinguished primary from metastatic adenocarcinomas. Solid tumors carrying this signature were most likely to be associated with metastasis and poor clinical outcome, suggesting that the metastatic potential of human tumors is encoded in the bulk of a primary tumor, rather than in just a small minority of the cells. The findings support the existence of a molecular program of metastasis that is shared by multiple types of solid tumors, suggesting the possibility of common therapeutic targets shared by different cancers.

Other solid tumors for which gene-expression profiling has proven a valuable tool for pattern-based class discovery and prognostication include gliomas (the most common malignant primary brain tumor) (Freije *et al*., 2004), kidney cancer (Vasselli *et al*., 2003), parathyroid tumors (Haven *et al*., 2004), leiomyosarcoma (sarcoma of the smooth muscle) (Lee *et al*., 2004), and prostate cancer (Lapointe *et al*., 2004), and more recently colorectal cancer (Eschrich *et al*., 2005). A gene expression–based classifier for gliomas was found to be a more powerful survival predictor than histologic grade or age (Freije *et al*., 2004). This classifier was validated with an additional external and independent data set from another institution, indicating that gene expression–based predictors are robust and can be applied across multiple institutions and platforms.

Vascular cell adhesion molecule-1 (VCAM-1) was found to be the gene most predictive in patients with kidney cancer, whose clinical course can be highly variable, with many patients dying within 1 year of diagnosis and others living for years with slowly progressive disease (Vasselli *et al*., 2003). Survival for patients with metastatic renal cancer was correlated with the expression of various genes based solely on the molecular profile of the primary kidney tumor.

Although parathyroid tumors are heterogeneous, histological differences are subtle, thus confounding classification. A class discovery approach identified three broad cluster groupings with possibly different molecular pathways of tumorigenesis (Haven *et al*., 2004). Similarly, a gene-expression signature, containing many genes previously reported to be associated with metastasis in a variety of cancers, was found to be predictive of metastatic outcome in leiomyosarcomas (Lee *et al*., 2004). And, for prostate cancer, three previously unknown subclasses were discovered with high-grade and advanced stage tumors disproportionately represented among two of the subclasses. Expression levels of MUC1, highly expressed in the more aggressive tumor subgroups, and AZGP1, highly expressed in the nonadvanced subgroup, were found to be strong predictors of tumor recurrence independent of tumor grade, stage, and preoperative prostate-specific antigen levels. Finally, for colorectal cancer, Eschrich *et al*. (2005) have identified a profile of genes with the potential to outperform Dukes' staging in predicting outcome for this disease. Of interest was that their classifier gene set was tested in an

independent Danish subpopulation with favorable results. Of the markers identified, osteopontin played a dominant role, and had been previously identified by the same laboratory using a pooled RNA approach with a different microarray platform and a different clinical endpoint (stage versus overall survival) (Agrawal *et al.*, 2002). The discovery of such differentially expressed genes as well as distinct molecular subtypes has great potential not only in uncovering new leads to understanding the mechanisms of cancer progression but also toward tailoring powerful and precise treatments to the individual patient.

2. Conclusions

The new insights into the complexity of cancer that are currently being generated by gene-profiling technology are certainly groundbreaking and exciting. Nonetheless, the true promise of molecular profiling lies in the translation of the technology into cost-effective clinical use. Many diagnostics and prediction assays are being developed at this time; however, as of today, none has undergone the scrutiny of prospective randomized trials. Once the scientific merits of gene expression–based therapy are firmly established, rational therapy may be designed on the basis of sound diagnosis, accurate prediction of response, and the likelihood of beneficial outcome. The clinical advantage and economic benefits of such advancement in cancer treatment will be enormous for the most important elements in this endeavor – our patients.

Short Specialist Review

Seven years of yeast microarray analysis

Gavin Sherlock
Stanford University, Stanford, CA, USA

Paul T. Spellman
Lawrence Berkeley Laboratory, Berkeley, CA, USA

1. Introduction

One of the specific goals of the Human Genome Project (*see* Article 24, **The Human Genome Project**, Volume 3), defined by the National Research Council study in 1988, was to sequence the genomes of a number of model organisms, with the expectation that an understanding of the genomes of model organisms would guide us in our investigations of the human genome. *Saccharomyces cerevisiae* was the first eukaryote to be fully sequenced, which revealed approximately 6000 simply constructed genes. At the same time, DNA microarrays were invented at both Stanford University and Affymetrix (*see* Article 91, **Creating and hybridizing spotted DNA arrays**, Volume 4 and Article 92, **Using oligonucleotide arrays**, Volume 4), yielding the ability to simultaneously quantify the abundance of thousands of nucleic acid species in complex mixtures. Easy genetic manipulation, compact gene structures and a complete genome sequence made yeast the center of genomics, and microarrays provided an unprecedented opportunity to assay an entire biological system. This short review examines the development of microarray technology, and the variety of innovative uses to which it has been put in furthering our understanding of yeast biology, illustrating how yeast was, and continues to be, at the forefront of genomic research (*see* Article 43, **Functional genomics in *Saccharomyces cerevisiae***, Volume 3).

2. Large-scale studies of gene expression

In 1997, Joe DeRisi and colleagues, from Pat Brown's laboratory at Stanford, published a landmark microarray study (DeRisi *et al.*, 1997). On the basis of the recently published genome sequence, the Brown and Botstein labs PCR-amplified 6400 predicted open reading frames from yeast, and spotted each PCR product to create the first whole-genome microarray in an 18 mm × 18 mm square.

DeRisi, Iyer, and Brown investigated the diauxic shift, which is the point at which yeast switch to ethanol as a carbon source, after having exhausted the available glucose. Seven samples taken every 2 h resulted in more than 43 000 expression measurements, their analysis of which showed that changes in gene expression during the diauxic shift result in metabolic reprogramming consistent with the environmental changes that were occurring.

The following year, two groups analyzed the transcriptional program of the yeast mitotic cell cycle, using high-density oligonucleotide arrays from Affymetrix (Cho *et al*., 1998), or homemade microarrays with spotted PCR products (Spellman *et al*., 1998, which includes the authors of this chapter). Together, they used four different methods of whole cell culture synchronization to determine the periodically transcribed genes through the cell cycle. While the two studies were not in exact agreement as to the number and identity of those transcripts, there was a large overlap in their findings. At that time, our cell cycle dataset was (and continued to be for some time) the largest single dataset published with microarray experiments from 62 unique arrays. It should be noted that both the Davis and Brown/Botstein groups made their data available on the Internet and that in our cell cycle study we actually reinterpreted the Davis lab data, which was the first time a dataset was reanalyzed. This marked the beginning of the age of microarray data reanalysis, with our study (and a number of the following studies) showing that complex reanalysis of yeast gene expression data was possible.

3. Yeast gene deletions and DNA microarrays

Concurrent to the efforts to characterize global gene expression profiles was an effort to generate systematic deletion mutants, a set of 24 000 yeast strains available as homo- and heterozygous diploids and as haploids of each mating type. This project was both driven by and drove microarray technology because Ron Davis' lab, in conjunction with Affymetrix, had developed a system of using a molecular barcode for each deletion, which could be detected by hybridization. In the proof of principle experiment, Shoemaker *et al*. (1996) demonstrated that these bar-coded yeast strains could be grown competitively under a given condition and the relative abundance of each strain could be assayed using microarrays to assess if deletion of a given gene resulted in a measurable quantitative trait.

Winzeler *et al*. (1999b) extended this approach by assaying complex mixtures of more than 500 homozygous bar-coded deletion mutants, under growth in either rich or minimal medium, to determine whether the deletion of these nonessential genes affected the fitness of the strains. While generation of the mutants initially was an enormous effort, the ability to rapidly assay their phenotypes in competitive mixtures was relatively simple to implement. Thus, after generation of the initial reagents, it is relatively easy to assay a large number of growth conditions to uncover the functional roles of previously uncharacterized genes.

A recently developed method, Synthetic Lethality Analyzed by Microarray (SLAM; Ooi *et al*., 2003), has taken this concept one step further. Instead of assaying the fitness of individual deletion mutants, a pool of mutants is transformed with a deletion construct for a gene of interest. Synthetic interactions are detected

using microarrays to determine if a deletion mutant in the original pool has been depleted. The advantage of this method over traditional screens of this nature, in addition to microarray identification of candidates, is that it is quantitative, and candidates can be ranked. Theoretically, it could also be used to find deletion mutants that enhance the ability of another deletant to grow.

4. Assaying drug modes of action

At the same time as the first whole genome expression studies were being carried out to characterize biological pathways in *S. cerevisiae*, Marton *et al*. (1998) demonstrated that expression signatures from deletion mutants treated with different drugs could be used to identify candidate drug targets. Their logic was that the typical drug-induced signature would be largely absent if the cell were deleted for the protein that was the target of the drug. Additionally, they characterized "off-target" effects, which remained even in the absence of the target, thus elucidating drug specificity. This result established that drug action could be systematically studied in yeast, which contains many genes for which there exist homologs in human cells.

Hughes *et al*. (2000) built on this idea and created a compendium of yeast gene expression data, generated both from deletion mutants and from cell treated with compounds with known molecular targets. Their goal was to construct a reference database of gene expression profiles, such that interpreting expression profiles of new mutants or cell treated with drugs of unknown targets could be done in the context of the preexisting data. If treatment with a drug resulted in a similar expression *signature* as resulted from deletion or mutation of a particular gene, then that drug may target that gene, either directly or indirectly. Hughes *et al*., as had Eisen *et al*. (1998) before them, were among the first to realize the cumulative value of microarray data and that different microarray experiments are not islands but instead each add to the value of the others, such that the sum of biology that can be derived from a global set is greater than that which can be derived from any single set alone.

5. Mapping traits using microarrays

In an illustration of the diverse applications of microarrays, Winzeler *et al*. (1998) used high-density oligonucleotide arrays to scan for allelic variation in the genome, on the basis of the premise that polymorphisms in the genomic DNA of an yeast strain would cause decreased hybridization to oligonucleotides that were designed on the basis of the sequenced strain of *S. cerevisiae*, S288 C. They were able to identify markers spaced roughly every 3.5 kilobases throughout the genome of a strain unrelated to S288 C. Using these markers, they were able to map the phenotype of cyclohexamide sensitivity in one of the parental strains unambiguously to the Pdr5 multidrug resistance pump. Steinmetz *et al*. (2002) extended this technique by identifying the causative alleles of quantitative trait loci (QTLs) responsible for a clinically important phenotypic trait in yeast, the ability to

grow at high temperature. In an even more far-reaching study, Brem *et al*. (2002) used the same technique as Winzeler *et al*. (1999a) to track genetic markers, but instead of scoring simple measurable traits in plate or growth assays, they measured considered genome-wide transcription as the phenotype. They used whole-genome microarrays to measure the expression of the two parental strains and 40 haploid segregants and were able to link the expression levels of 570 genes to one or more loci. Furthermore, they identified eight loci that appeared to encode trans-acting factors responsible for some of the expression variation that they observed. Thus, microarrays can be used to track both genome-wide genotypes and genome-wide phenotype, and identify causative linkages between them.

6. Systems biology

While there are many applications of microarrays that can be used to probe the state or contents of a cell or biological system, microarray data can be greatly enhanced by the addition of other systematic data. In an attempt to characterize the network of interactions that control galactose metabolism, Ideker *et al*. (2001) systematically perturbed the galactose metabolic network, both genetically and environmentally. They used microarrays to assay the gene expression changes, and tandem mass spectrometry of tagged proteins to assay changes in protein abundance for several hundred proteins. These data were then combined with preexisting 2-hybrid interaction data and protein–DNA interaction data from transcription factor databases to build a model of galactose metabolism within the cell. The approach of combining microarray data (potentially of different types) with other functional genomics data is likely the way by which we will elucidate how a cell works as a system.

7. Assessing the state and content of the genome

Raghuraman *et al*. (2001) used microarrays to define Origins of Replication for the whole genome using microarrays. Using the classic, Heavy/Light isotope trick, they purified EcoRI fragmented DNA whose ratio of Heavy to Light isotopes depended on proximity to an origin. Comparing Heavy–Heavy and Heavy–Light fractions by hybridization to a microarray identified regions of the genome that acted as ARS and determined when they fired in the cell cycle as well as fork migration rates.

8. Identification of protein–DNA binding sites

One of the most important advances in moving toward a full systems biology approach is the use of DNA microarrays to determine the in vivo binding sites for transcription factors using Chromatin immunoprecipitation (ChIP). Rick Young's group at MIT was the first group to microarray-based ChIP data (Ren *et al*., 2000), characterizing genes whose regulatory regions are bound by Ste12 and Gal4.

They followed up this result with a truly impressive body of work, systematically studying 106 yeast transcription factors to determine their in vivo specificities (Lee *et al*., 2002). In this one paper, they were able to characterize nearly all of the sequence-specific transcription factors and were able to identify network motifs, such as autoregulation, multicomponent loops, and feedforward loops. These data were used, in conjunction with other existing expression data, to produce network models for various cellular machinery, such as the cell cycle.

9. Protein chips

While the majority of microarray experiments have used DNA fragments on the microarray, either oligonucleotides, PCR products, or cDNA clones, protein microarrays have also been developed. Zhu *et al*. (2001) purified proteins encoded by 5800 different yeast ORFs, and then spotted the purified proteins onto a glass substrate to create a protein microarray. The microarray was then used to screen for proteins that interacted with calmodulin or phospholipids. This approach allowed them to identify a putative calmodulin-binding site that was present in many of the proteins that interacted with calmodulin. Again, while the initial reagents are time-consuming to prepare, once they are in hand, they can rapidly be used to assay various properties of proteins.

10. Summary and future

Since their development in 1996, microarrays have become a powerful tool in the biologists' arsenal. While they are most often thought of in connection with microarray expression studies, several landmark studies have demonstrated a wide variety of applications for microarrays, the majority of which were carried out in yeast. Using microarrays, researchers are able to assay almost every aspect of a living cell to characterize it, from the parental origin of genes, to their copy number, to the replicative state of the genome, to many aspects of the transcriptome and its properties, to the proteome itself (Figure 1). Owing to space constraints, we have limited the scope of our review but we would like to point out that microarrays have been used to study RNA stability and decay, RNA splicing, transcript length, RNA localization, and even the kinetics of protein translation (Holstege *et al*., 1998; Wang *et al*., 2002; Grigull *et al*., 2004; Clark *et al*., 2002; Hurowitz and Brown, 2003; Marc *et al*., 2002; Arava *et al*., 2003). Furthermore, microarrays can be used as a screening technology to identify the effect upon the fitness of a cell in the presence of various deletions or mutations.

Great strides have been made in understanding several fundamental aspects of yeast cell biology using microarrays since 1996, yet by no means can we say that yeast is "solved" as an organism. First, and most surprisingly, we do not yet know with certainty the number and location of all yeast genes nor do we know the set of transcripts produced from these genes. Second, we do not know the functions of almost one-third of the genes that are identified. Tiling arrays, in which nearly the entire yeast genome sequence can be interrogated, will enable us to elucidate all the transcripts encoded by the genome and accurately

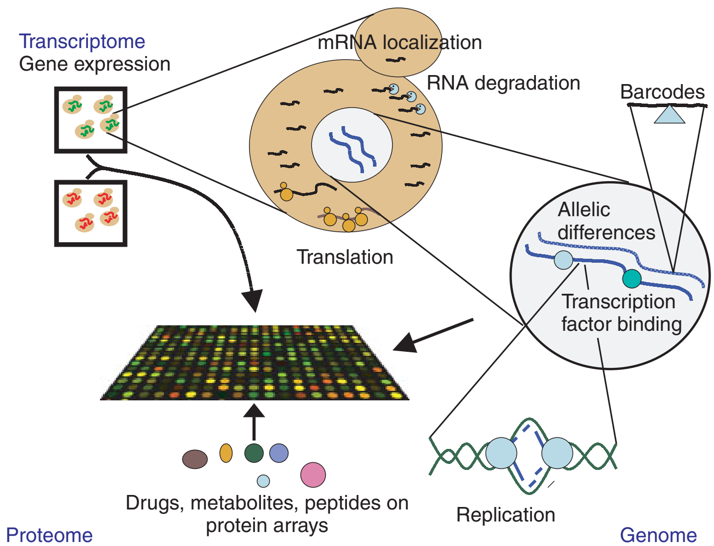

Figure 1 Illustration of an yeast cell to show how microarrays can be applied to interrogate all aspects of the central dogma of molecular biology. In the central dogma, DNA (the genome) is used as a template to make RNA (the transcriptome), which in turn is translated into protein (the proteome). Although microarrays are often thought of in connection with assaying transcript abundance, they can be used to assay various properties of each of the aspects of the central dogma, as shown

determine their 5′ and 3′ ends. It is unclear at this point how many additional, as yet unrecognized genes exist in the genome, and how many of those currently marked as dubious by the community database, SGD (Christie *et al*., 2004) really have no function, or do not produce a transcript. Comprehensive understanding of yeast biology on an organismal scale requires additional microarray experiments, using more comprehensive microarrays, coupled with the integration of additional nonmicroarray data types, such as 2-hybrid and other protein–protein interaction data. In addition, it will be necessary to integrate these results with a comprehensive analysis of the yeast metabolome. Once we understand, through experimentation, how all the components in the central dogma fit together (the genes in the genome, when and what transcripts are produced, and the functions of the encoded products) and how the metabolites and their abundance and fluxes change during various physiological programs, we will understand, to a first approximation, how yeast works on an organismal level. Application and extension of the fundamental principles that have been learned from such studies will be instrumental in understanding how more complex, multicellular organisms work.

Short Specialist Review

Bacterial genome organization: comparative expression profiling, operons, regulons, and beyond

Scott N. Peterson
The Institute for Genomic Research, Rockville, MD, USA
The George Washington University, Washington DC, USA

1. Bacterial ecosystem diversity is mirrored at the level of the genome

The diversity of bacterial species is not known, however, it has been estimated that less than 1% of the bacterial species have been characterized to date (DeLong and Pace, 2001). Bacteria occupy virtually every ecosystem present on our planet, including "extreme" environments wherein certain bacteria survive in temperatures greater than 110°C or less than −10°C, ranges of pH from <1.0 to >9.0, salt concentrations as high as 5M NaCl, and pressures in excess of 130 Mpa (Rothschild and Mancinelli, 2001). Since the environment provides the selective pressure responsible for bacterial genome evolution, the wide diversity of environments occupied by microbes offer a partial explanation for the genomic diversity observed thus far. A major insight resulting from widespread sequencing of bacterial genomes is the apparent prevalence of gene acquisition through horizontal gene transfer events in bacterial genome evolution (Lawrence and Hendrickson, 2003). DNA sequence data (from more than 130 microbial genomes) indicate that bacterial chromosomes come in a wide variety of shapes, sizes, and gene complements, and emphasize that exceptions are the rule in bacterial genomics. One genomic feature conserved in all bacterial genomes is the organization of genes in cotranscribed clusters referred to as *operons*. Conserved genomic features shared among all characterized bacteria are rare and thus justify the importance that we attribute to them.

The universal occurrence of operons in bacterial genomes strongly suggests that the selective forces responsible for their formation are powerful and pervasive. The "selfish operon" model is based on the assumption that horizontal gene acquisition is the force that drives operon formation (Lawrence and Roth, 1996). Alternative models involving tandem gene duplication have also been proposed (Reams and Neidle, 2004). Genes located within operons frequently encode proteins that act in concert to carry out a specific function, such as steps in a metabolic

pathway. According to the selfish operon model, the functional congruency of genes within operons is a natural consequence of the fact that the inheritance of novel, advantageous, multigenic traits can only be coselected and fixed in the genome if all required genes are acquired in a single DNA acquisition event. Most genes within horizontally acquired genomic fragments provide no selective advantage to the host and are lost over time, thereby increasing the physical linkage of coselected genes. The increased physical linkage between coselected genes further increases the probability that they will be coacquired in a single event. This self-perpetuating process may reach a practical end point when coselected genes achieve maximal linkage. The fact that coregulated genes tend to be "like-minded" with respect to function is a useful means of forming hypotheses pertaining to the function of genes of unknown function (at least 30% of all genes in microbial genomes). A refinement of this idea considers the conservation of gene linkage across bacterial species as a means of increasing the power of functional predictions (Overbeek *et al*., 1999). Operon structure (gene identity and order within the operon) while sometimes conserved is more frequently variable, especially over large phylogenetic distances (Lathe *et al*., 2000; Wolf *et al*., 2001). The heterogeneity of operon structure may result from numerous opposing evolutionary forces that generate heterogeneity in bacterial populations through genome rearrangements, mobile elements, and recombination. It is important to remember that a genome sequence represents a "snapshot" of evolution and as such is a "work in progress".

2. Global analyses provide a new way to visualize microbial genomes

There are an increasing number of algorithms being applied to identify functional elements within genomes, such as transcriptional terminators (Ermolaeva *et al*., 2000), DNA regulatory motifs (Roth *et al*., 1998; McGuire *et al*., 2000), and operons (Salgado *et al*., 2000; Ermolaeva *et al*., 2001). The sensitivity, specificity, and precision of operon, promoter, and transcription terminator identification are ever improving and are remarkably efficient at identifying these genomic elements (Bockhorst *et al*., 2003). Experiments to better define the *Escherichia coli* transcriptome, using high-density Affymetrix chips, confirmed the existence of many previously predicted transcription units (operons) and identified many novel transcripts, particularly those expressed from small open reading frames (Tjaden *et al*., 2002; Bockhorst *et al*., 2003). The colocalization of genes exhibiting similar transcriptional behavior represent a powerful means of defining operon structure and simultaneously suggest where 5′ promoter elements are likely to reside. Transcription unit (operon) definition, whether achieved experimentally or computationally, are complementary and promise an enhanced ability to experimentally test computationally based motif predictions. Likewise, experimental datasets will aid in the validation and improvement of future motif-finding algorithms. Tjaden and colleagues assessed gene expression of *E. coli* grown in minimal and rich medium, at four distinct growth phases, both aerobically and anaerobically. The semi-independent nature of each growth condition examined

provided a dataset wherein the complexity of gene expression inherent to each growth condition can be dissected, and in some cases, allows one to define a regulon (a group of coregulated operons). For those attempting to understand the relationship between cellular signals and the associated gene expression response, it is useful to view bacterial genomes not as a set of genes but as a set of operons and regulons. It is likely that an understanding of transcription will require a detailed understanding not only of operons and regulons but also of their interaction and cross-talk under specific environmental conditions.

3. Global gene expression analysis of *S. pneumoniae* competence development

Streptococcus pneumoniae cells growing at low cell densities produce and respond to a signal transduction, competence stimulating peptide (CSP). Cells exposed to CSP undergo a rapid and synchronous response resulting in competence (DNA uptake and genomic integration) (Morrison and Baker, 1979). At the molecular level, it had been established that CSP induces a cell signaling cascade, resulting in the upregulation of various RNA transcripts and proteins required to mediate the uptake of extracellular DNA and its subsequent homology-dependent introduction into the genome, mediated by recA (Havarstein *et al*., 1995; Peterson *et al*., 2000; Rimini *et al*., 2000). The global gene expression analysis using DNA microarrays identified all 40 previously known and 84 new CSP-induced genes (Peterson *et al*., 2004a,b). Induced genes exhibit three discrete temporal phases of activation. The first wave (max = 7.5 min post-CSP) of transcripts includes those encoding CSP and the membrane apparatus for its export (signal amplification), transcriptional regulators, known to regulate early and late gene expression and a set of genes related to bacteriocin production. The second wave (max = 12.5 min post-CSP) of transcriptional activation (81 genes) encodes proteins required for DNA uptake, processing, and recombination. The final wave (max = 20 min post-CSP) includes 20 genes encoding a complete set of heat shock effectors. Concurrent with our gene expression analysis, members of Don Morrison's laboratory (The University of Illinois, Chicago) constructed and analyzed numerous mutant strains bearing deletions in CSP-induced genes. Among the 91 genes analyzed, 23 were essential for growth, whereas 67 were individually dispensable for competence development. Only one new essential gene (unknown function) was identified. Despite the high efficiency with which global gene expression analysis identified CSP-induced genes, it was surprising that such a great fraction of those genes appeared to be dispensable for competence development.

4. Molecular dissection of DNA double-strand break repair in *D. radiodurans*

Deinococcus radiodurans is best known for its extraordinary resistance to ionizing radiation (X rays). The molecular events associated with this resistance remain largely uncharacterized. *D. radiodurans*, like many other bacteria, maintains its

genome (two chromosomes and two extrachromosomal plasmids) in multiple copies and is able to repair as many as 150 DNA double-strand breaks in a recA-dependent process. Remarkably, the recovery of cells following high exposures of ionizing radiation (5 kGy) occurs without lethality or apparent mutagenesis (Battista *et al*., 1999). The cell density of cultures begins to increase within 60 min following irradiation, suggesting that the repair of DNA double-strand breaks and the oxidative damage caused by radiation-dependent free-radical formation is complete in some cells within the population (Tanaka *et al*., 2004). *D. radiodurans* is also unusually resistant to a number of other stresses, such as desiccation, UV radiation, heat, oxidative damage, and osmotic stress. It has been speculated that the wide array of resistance observed in *D. radiodurans* arose primarily as an adaptation to survival in desiccating environments (Battista, 1997). Analysis of the *D. radiodurans* genome sequence revealed a rather ordinary repertoire of DNA metabolism and repair genes and, therefore, few clues to help explain the observed resistance of this bacterium (White *et al*., 1999). Mattimore and Battista (1996) established a connection between the resistance to ionizing radiation and desiccation genetically by demonstrating that a collection of *D. radiodurans* radiation sensitive strains were also sensitive to desiccation, suggesting a shared molecular basis for the two resistance profiles.

Since desiccation also generates DNA double-strand breaks, we exploited the established association between resistance to ionizing radiation and cellular desiccation to identify functionally important genes involved in DNA double-strand break repair. Since cellular desiccation and the delivery of high doses of ionizing radiation are not instantaneous, our expression analyses examines a transcriptional response already in progress and therefore does not capture the onset and induction kinetics of the induced genes. The gene expression changes in response to ionizing radiation and cellular desiccation are of limited complexity and, somewhat unexpectedly, small in magnitude (Tanaka *et al*., 2004). A total of 72 genes (2.2% of genome) were induced following exposure to ionizing radiation (3 kGy), of which the majority encoded functions belonging to three functional classes. The largest class (32 genes, 44%) encodes proteins of unknown function. The second group (*recA, ruvB, uvrA, uvrB, gyrA,* and *gyrB*) encodes functions involved in DNA metabolism. Five genes with an apparent role in oxidative damage protection make up the third class. The gene expression pattern associated with recovery of cells from desiccation (5% humidity) involved 73 genes, of which 33 were in common with those induced in response to irradiation. Among the overlapping transcripts were all six DNA metabolism and repair genes and 21 genes of unknown function; only two of the five genes associated with adaptation to oxidative stress were induced in cells recovering from desiccation.

The five most highly induced genes were identical in both responses and encode proteins of unknown function. Mutational analysis of strains bearing deletions of these five genes individually and in all pairwise combinations revealed that these genes encode proteins that participate in both recA-dependent and independent processes. Only three of the five single gene knockout strains displayed increased sensitivity to ionizing radiation.

This poor correlation between gene activation and functional essentiality appears to mirror that observed for *S. pneumoniae* competence development. However,

when these single gene deletions were examined in pairwise combination and in a *recA*-deficient background, a different picture emerged. Two of the proteins were shown to possess partially redundant or complementary activities. With the exception of paralogous gene families, functional redundancy in bacterial genomes is, to some extent, unexpected.

The overrepresentation of genes of unknown function in *D. radiodurans* related to DNA damage repair strongly imply that this process occurs either by a largely novel mechanism or by well-characterized mechanisms involving genes bearing little sequence identity to functionally equivalent proteins found in other bacteria. The lack of sequence identity between DNA repair proteins in *D. radiodurans* to other bacterial proteins may not be a simple matter of divergent evolution but rather the consequence of nonorthologous gene relationships. Nonorthologous genes encode proteins that perform identical or similar functions within a cell but owing to their independent evolution have no ancestral relationship to their functional counterparts in other species. In other words, nonorthologous genes are those that have evolved more than once during evolution. Examples of nonorthologous genes have been identified in nature (Koonin *et al*., 1996). The fact that each successive microbial genome sequencing project reveals a set of genes of unknown function at nondeclining frequency suggests that nonorthologous genes may be prevalent and as such pose a daunting problem within the field of microbial genomics. The assignment of gene function based on sequence identity (orthology) has had enormous impact on our ability to "understand" genomic sequence information. In the absence of orthology, the only means of obtaining information on the function of a protein is through focused laboratory experimentation. It is conceivable that our reliance on the functional data generated as the result of the efforts made in a few select model systems, while powerful, cannot account for all of the coding potential in any genome. It is possible that the next phase of genomics effort should address this question in more detail and that ultimately functional characterization of lesser known bacterial models will be required if we hope to reinvigorate the orthology-based functional assignments that we have come to rely so heavily upon.

5. Transcriptional analysis of *Bacillus anthracis* sporulation and determination of the endospore proteome

The dormant spore of *Bacillus anthracis*, the bacterium thought to cause anthrax, is the infectious agent. Upon entry into a host through inhalation, the spore efficiently infects macrophages where it rapidly germinates within the harsh environment of the phagolysosome (Guidi-Rontani and Mock, 2002). The determination of the gene expression in *B. anthracis* cells undergoing sporulation (induced by nutrient starvation) and of the spore as it germinates are of fundamental interest. We recently reported on the gene expression during sporulation and the protein content of the spore as determined by multidimensional chromatography and tandem mass spectrometry (Lui *et al*., 2004). The combined use of these two global approaches provided a means of relating the observed gene expression to the proteome of the spore itself. We compared the RNA expression patterns of 20 samples (15-min intervals) over a 5-h period corresponding to exponential, nonexponential, and

stationary phase growth, as well as, the entirety of sporulation. It is known that the onset and progression of sporulation in the closely related *B. subtilis* involves the sequential activation of a number of sigma factors that mediate and coordinate the temporal expression of the so-called sporulation genes (Kroos and Yu, 2000). In *B. anthracis*, a significant and reproducible change in gene expression was observed for over 3500 genes (63% of the genome). Just over 2000 genes displayed growth-phase regulated expression in two or more consecutive time points (>30 min). Hierarchical clustering of the expression data revealed a complex set of expression patterns. Through a slightly oversimplified view of the data, the gene expression patterns can be represented by five distinct patterns, based on the temporal onset of gene expression changes (activation or repression). These five patterns appear to correspond to biologically meaningful phases, as judged by the number of transcripts and transcriptional regulators involved at each phase. Approximately 1100 genes displayed altered RNA expression within the first two phases, which correspond to cells exiting exponential growth phase and entering stationary phase growth and stationary phase growth just prior to the onset of sporulation. The heterogeneity of transcriptional behavior among genes within these two phases is substantial especially when compared to the transcript profiles corresponding to ~900 genes observed in the subsequent three phases occurring during sporulation.

Once inside the macrophage, the *B. anthracis* spore enters into a race with the host immune response. Consequently, the spore has become uniquely adapted to germinate and begin vegetative growth rapidly. For this reason and others, it had been assumed that the spore contained proteins to ensure efficient reentry into a growth phase. Among the 750 proteins identified in the endospore, half are encoded by genes expressed constitutively throughout the entire experimental time course. Consistent with prior assumptions, these transcripts encode proteins biased in functional representation, the most overrepresented classes being those involved in protein synthesis, nucleoside/tide biosynthesis, and energy metabolism. The remaining half of the endospore proteome is composed of proteins encoded by genes displaying altered RNA expression in each of the five expression phases in approximately equivalent proportions. It was not anticipated that gene expression changes occurring during the first two growth phases would contribute equally to the endospore as genes differentially expressed during sporulation. It is somewhat surprising that approximately 15% of the spore proteome is derived from strongly repressed genes, an interesting subset of which are upregulated (~75 min) as cells enter saturation phase. These genes are subsequently repressed as cells enter into sporulation. This gene expression pattern may suggest that preparations for sporulation occur prior to the cell's actual commitment to this pathway. It is noteworthy that less than 20% of the genes displaying sporulation-limited RNA expression encode proteins present in the endospore. Taken together, the two global analyses support the view that *B. anthracis* sporulation is a highly controlled and complex process. The proteins (raw materials) and enzymes (tools) required to construct and load the endospore are expressed in a growth-phase dependent and independent manner. The proteins encoded by genes displaying sporulation-specific expression contribute several functions related to the structure and architecture of the endospore. The function and significance of many proteins differentially expressed during

sporulation remain to be determined. However, our data suggest that the majority of differential gene expression associated with sporulation is intended to provide proteins required for the processing of the raw materials and the physical construction of the spore. In this regard, the spore, like most building projects, necessitates the acquisition of a specialized set of tools and "some assembly is required".

6. *S. pneumoniae* growth-phase-dependent gene expression: comparative expression profiling (CEP)

Growth-phase-dependent gene expression in *S. pneumoniae* is of comparable complexity (∼1000 genes) to that observed in *B. anthracis* but represents a significantly greater proportion of its genome's coding capacity (∼45% compared to ∼22% for *B. anthracis*). In *S. pneumoniae*, the majority (90%) of growth-phase-regulated genes are downregulated as cells entered stationary phase growth. The potential commonality of cellular signals (e.g., glucose limitation) generated by cells as they enter saturation phase growth provides an opportunity to determine whether the comparisons of gene expression profiles, as illustrated by the *D. radiodurans* study, can be fruitfully applied to a wide range of species. We refer to this approach as comparative expression profiling (CEP). *B. anthracis* and *S. pneumoniae* are both members of the low G+C gram-positive lineage. *S. pneumoniae* does not sporulate in response to nutrient limitations. It is possible that aspects of the transcriptional and metabolic response to nutrient limitation are common to these distantly related cousins. Nutrient limitation may represent a primordial selective pressure faced by all bacterial species throughout time. Given the potential commonality of the selective pressure, we were interested in determining whether mechanisms to cope with nutrient limitations are highly conserved across species. Early stage analysis of the differentially regulated genes in *S. pneumoniae* indicates that a large number of similarities and differences exist to growth-phase-regulated genes in *B. anthracis*. This comparative analysis may also allow us to refine our focus toward those genes specifically related to and functionally required for sporulation and endospore formation (Figure 1).

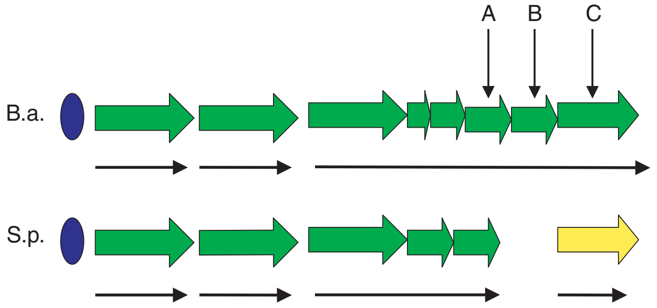

Figure 1 Comparative expression profiling (CEP)

7. The relationship between gene expression and functional significance: *S. pneumoniae* competence gene expression revisited

The universal occurrence of operons in bacterial genomes and the organization of genes encoding proteins of functional relationship in cotranscribed operons and coexpressed regulons are consistent with the frugality and efficiency that we expect from bacteria. The fact that only 18% of the genes differentially expressed in response to CSP in *S. pneumoniae* appear to be essential for wild-type competence development suggests a lack of frugality inherent to this response. While performing CEP using the *S. pneumoniae* competence and growth-phase gene expression data, a fortuitous observation was made. There was a total of 34 genes differentially expressed in both studies. Upon closer inspection, the transcription units predicted by several CSP-induced genes differed from those predicted by the growth-phase expression study. The most compelling interpretation of this observation is that many of the genes induced during competence development are the result of failures to terminate transcription efficiently. Potential transcriptional read-through affecting 37 genes (4 early, 33 late) was noted. Overall, this modification increases the percentage of essential genes induced during competence development to 27%, a value that still falls short of our expectations of a highly evolved bacterial system. The 22 gene products whose functions are required for competence reside in 13 operons (5 early and 8 late). All of the genes (8) within the five early operons are essential, whereas 14 of the 19 genes present in the eight late operons are essential. All instances of "read-through" transcription occurred downstream of the previously characterized promoter motifs associated with early and late gene expression and correlated with the transcripts undergoing the largest increases following CSP-induction (~100- to 1000-fold, Snesrud *et al*., 2004). The relationship between promoter strength and the occurrence of read-through transcription is not yet clear and may be trivially related to the ease of detection for highly expressed genes. Alternatively, it may be that some operons contain weak transcriptional terminators "by design" (see below).

A useful concept in microbial genomics invokes a view of genomes as consisting essentially of two types of genes, a core set of conserved functions required for cell growth and existence and a larger set of conditionally dispensable contingency genes that provide the broadened functional repertoire demanded for success in a particular microenvironment (Mushegian and Koonin, 1996; Peterson and Fraser, 2001). It may be that the competence regulons can be viewed in a similar manner. In this regard, 22 of the 27 core competence genes (81%), residing in 13 operons, expressed are essential for wild-type competence. A larger set of nonessential genes such as those mediating chaperonin and proteins folding and degradation and those involved in bacteriocin production that are not required for competence may provide subtle fitness advantages to the cell. Another possibility suggested by a parallel study to our own is that CSP-induced genes play a role in a phenomenon referred to as *saturation phase cell autolysis* (Dagkessamanskaia *et al*., 2004). Competence, a low-cell-density phenomenon, is not detectable in saturation phase cultures where autolysis occurs. The possibility that CSP-induced regulons play a role in biological

processes other than competence suggests that it is our expectation that differentially expressed genes be functionally required that is misguided. Genes within operons deemed dispensable for wild-type competence may encode proteins with activities required for cell autolysis and vice versa. Stationary phase autolysis is known to be mediated by *lytA* by an unknown mechanism (Tomasz and Zanati, 1971). It is interesting that *lytA* is induced in response to CSP as the result of transcriptional read-through and serves as fair warning not to be too hasty to assume that the role of CSP-induced operons in stationary phase autolysis is a biological anomaly. After all, it is through "accidents" that genomic novelty and expansion of functional capabilities are achieved in nature. It is conceivable that only a small number of genes in any genome are dedicated to functin in a single scenario. The induction of operons in multiple cellular contexts wherein the definition of essentiality is dynamic support the viewpoint that despite appearances, gene organization within bacterial genomes is remarkably efficient and may account for bacteria's ability to respond to a wide variety of environmental signals with a relatively limited number of genes.

8. Summary and conclusions

The conservation of gene pair (coexpression) relationships across species has been used extensively as a predictor of protein interaction pairs and the coparticipation of proteins in the same cellular process. In this manner, CEP represents an extension of the same idea. The application of CEP to closely related species may enhance the identification of the core gene sets that are functionally required to accomplish the cellular response under investigation. When applied to species of distant phylogenetic relationships, CEP may provide a systematic means of identifying candidate nonorthologous gene relationships and, more importantly, valuable clues to those scientists attempting to functionally annotate those genes. Ultimately, our ability or inability to interpret global gene expression is primarily limited by our knowledge of the number and identity of pertinent cellular signals and/or the details of the molecular events associated with the response to those signals. The expansion of tools and methods used for gene expression data "mining", together with the efforts of computational biologists generating high-quality predictions of regulatory sequences and transcription units in bacterial genomes, will allow our understanding of the complexities of gene regulation at the level of the operon and regulon to reach new heights. As we begin to document the interplay and cross-talk occurring between regulons in various physiological contexts, we are certain to gain a greater understanding of bacterial genome evolution and define new inroads for the development of antimicrobial therapies.

Short Specialist Review

Genomic analysis of host pathogen interactions

Paul Kellam and Catherine V. Gale
University College London, London, UK

In the era of postgenomic biology, an area of much interest is how a multicellular organism interacts with the microbial world. This is perhaps not surprising when one considers the importance the human body places on protection from microbes. At a very rudimentary level of classification, of the approximately 200 cell types of the human body, 20 are concerned entirely with protection of the host from microbial attack. This review is broadly applicable to all types of pathogen, however, we will focus primarily on viral infections because of the close association between virus life cycles with the host cell environment.

Of the available postgenomic tools for the investigation of host pathogen interactions, gene expression profiling currently seems the most useful. This is aided by the fact that microbes often interact with host cells that are homoeostatically stable and therefore are in relatively steady state with respect to gene expression dynamics. Microbial encounter results in one of three outcomes although transition between the states can occur, namely, acute pathogenic microbial replication resulting in either host death or resolution of infection; microbial persistence without overt pathology and without microbial clearance; or commensalism where the microbe and host exist in a mutually beneficial way. In all cases, the major effect on host cells and tissues is a remodeling of their gene expression program to accommodate or combat the particular microbial exposure (Kellam, 2001). Dynamic changes in host gene expression programs are seen in the large number of studies where microarrays are used in an infection context (Figure 1) (Kellam, 2001; Bryant *et al*., 2004; Fruh *et al*., 2001). However, only recently has the data become of sufficient size to allow computational integration (Jenner and Young, 2005). Overall, common gene expression programs can be identified in many cell types, revealing a coordinated view of expression for many known infection-responsive genes. These include cytokines and chemokines, genes involved in the innate antiviral responses, especially interferon-inducible gene sets, cell cycle control, and apoptotic control gene sets. Gene expression profiling studies have shown that these common cellular responses to infection can be induced by related viruses, but by different mechanisms. Exposing human embryonic lung (HEL) cells to either IFN-α or a herpes simplex virus KM110 that contains inactivating mutations preventing lytic viral replication produce a very similar remodeling of the cellular transcriptome (20 of 27 modulated genes were induced by HSV-1

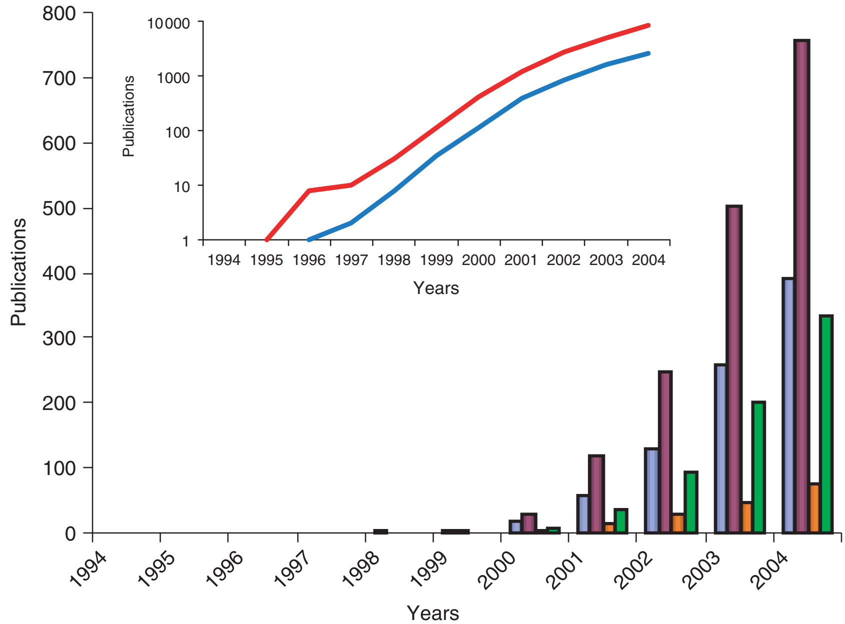

Figure 1 The continuing rise in the use of microarrays in infectious disease research. Pubmed (**http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=pubmed**) was searched with the terms "*microarray*" (red line, inset graph), "*cancer and microarray*" (blue line, inset graph), "*bacteria and microarray*" (purple bar), "*virus and microarray*" (blue bar), "*immune and microarray*" (green bar), and "*(host and pathogen) AND microarray*" (orange bar) for each year, with the number of publications recorded. While this is a crude relative measure, it serves to illustrate the trends of cancer biology driving the rapid rise in microarray usage, but with other areas of biology such as infectious disease research adopting microarray methods from the late 1990s onward

KM110 and IFN-α) (Mossman *et al*., 2001). The effects of the HSV-1 mutant occurred following the internalization of the viral particles but in the absence of viral gene expression, suggesting that HSV-1 activates an intracellular sensor that induces IFN-responsive genes at an early step during virus infection. In contrast, the herpesvirus, human cytomegalovirus (HCMV) induces IFN-responsive genes in primary human fibroblasts following attachment of virions to an unknown cellular receptor. In this context, the HCMV envelope glycoprotein B is necessary and sufficient for the IFN response. As with HSV-1, this happens in the absence of viral gene expression, but in contrast to HSV-1 occurs before virion internalization (Boyle *et al*., 1999), demonstrating that different cellular interactions, with distinct viruses, can converge on common antiviral transcriptional programs.

The infected cell transcriptome must, however, be put into context. Virus-infected cells in a host organism do not exist in isolation. The integrated induction of the innate and adaptive immune response to combat an infection requires the activation and terminal differentiation of diverse hematopoietic cell types. This multicell-type immune response, coordinated through transcriptional reprogramming of diverse hematopoietic cells, is therefore intimately coupled to the infected cell response. At the level of the innate arm, pathogen encounter by professional

antigen-presenting cells such as macrophages and (monocyte derived) dendritic cells, which share 96% of expressed genes prior to antigen encounter (Chaussabel *et al*., 2003), results in conserved macrophage or dendritic cell transcriptional responses that can be interpreted as "core" effector responses for the presence of a pathogen (Chaussabel *et al*., 2003; Nau *et al*., 2002; Huang *et al*., 2001; Ehrt *et al*., 2001; Granucci *et al*., 2001). The degree of transcriptional programs conservation between macrophages and (monocyte derived) dendritic cells to the same pathogen is less, with only 40% of the regulated genes being shared by both cell types (Chaussabel *et al*., 2003). These transcriptional changes are most likely due to the pathogen-specific engagement of a repertoire of innate immune receptor molecules such as the toll-like receptors (TLRs). The combinatorial integration of such receptor stimulation results in the induction of both the "core" activation and maturation pathways together with pathogen-specific transcriptional responses. This has been demonstrated in detail for macrophages and (monocyte derived) dendritic cells for distinct bacterial pathogens (or pathogen components) (Chaussabel *et al*., 2003) and for (monocyte derived) dendritic cells for diverse pathogens such as the yeast *Candida albicans*, the bacteria *Esherichia coli*, and Influenza Virus (Huang *et al*., 2001). In this context, diverse pathogen input into signaling pathways results in pathogen-specific outputs. Whereas this may be expected for professional antigen-presenting cells, allowing the formation of pathogen-encoded bridges between the innate and adaptive immune response, it raises the question as to what level other cell types respond differently to related or diverse pathogens.

Different herpesviruses infecting the same cell type show how viruses influence discrete transcriptional networks. An extensive study of the alphaherpesviruses Pseudorabies virus (PRV), and HSV-1, infecting rat embryonic fibroblasts was analyzed by grouping coregulated genes into functional pathways. This showed that both viruses upregulated 32% of cellular genes consistently, such as the insulin growth factor pathways and apoptosis pathway components (Ray and Enquist, 2004). Interestingly, the two viruses also differentially regulated important functional pathways, with PRV downregulating Notch pathway components and HSV-1 upregulating interferon and interleukin 1 pathway components. Differences in cellular responses at much lower levels of viral variation are also seen in studies addressing the impact of viral strain variation on gene expression and the potential functional relevance. Most of these studies address the issue of intraspecies variation by looking at examples where clear differences in infection phenotype lie. For example, a comparison of adenovirus type-5 and -12 transformation of human embryonic retina, kidney, and lung cells revealed differential gene expression of TGFβ factors that might contribute to the differences in oncogenic behavior of these two viruses (Vertegaal *et al*., 2000). Similarly, differential expression of proinflammatory cytokines in response to pathogenic and nonpathogenic pneumovirus infection, in a mouse model, have been described (Domachowske *et al*., 2002). Microarrays have also been used to propose a model of cell cycle control by reoviruses that differs between two viral serotypes (Poggioli *et al*., 2002) and define the molecular mechanism of pathogenesis of the hantaviruses, Sin Nombre and Prospect Hill (Khaiboullina *et al*., 2004). In addition, a study of different measles virus strains has also showed differences in host cell gene expression patterns that could help explain their distinct growth phenotypes in vitro, although the

problem of low multiplicity, asynchronous infection on a variable cell substrate, make analysis difficult in this case. It is becoming increasingly evident that this problem is common when low titer viruses are studied (Bolt *et al*., 2002), and great attention to the virology of such experiments will be required to extract biological meaning and functional relevance from these intraspecies comparative studies.

At a whole-organ level, gene expression profiling of Hepatitis B (HBV) and C (HCV) viruses has also revealed that viruses can influence common cellular environments in different ways, in these cases causing hepatocellular carcinoma (HCC) by distinct mechanisms (Iizuka *et al*., 2002; Okabe *et al*., 2001). HBV and HCV chronic hepatitis could be distinguished on the basis of differentially expressed genes. A broad analysis of the types of genes involved showed that HBV upregulated genes involved in apoptosis, cell cycle arrest, and extracellular matrix degradation, whereas HCV upregulated genes involved in cell cycle acceleration and extracellular matrix storage. The major difference between HBV- and HCV-derived tumors was the upregulation in HCV and downregulation in HBV of genes involved in activating chemotherapeutic drugs or detoxifying xenobiotic carcinogens. This suggests that a greater contribution of carcinogenic metabolites may be involved in the development of the HCV-associated tumors and that decreased expression in HBV HCC is specific for this virally derived tumor type. The gene expression differences in the two HBV/HCV studies reflect the fact that HBV and HCV are unrelated viruses that infect the same organ. They may also reflect, however, the fact that the viruses infect common cell types at different stages of the cellular differentiation and development and alter the cellular transcriptome at the stage infected.

Gene expression profiling in viral oncogenesis illustrated above for HBV and HCV raises the possibility that viruses are able to manipulate intracellular transcriptional programs to drive the infected cells to a different state that is beneficial to the virus life cycle. Ultimately, this is likely to be a rationale for all viral remodeling of host cell transcriptional environments. When the virus life cycle results in persistent infection, however, this trade-off between virally induced processes and the cellular defense system must be well balanced. Perhaps the greatest evidence for this comes from the studies of human herpesvirus 8, also known as Kaposi's sarcoma associated herpesvirus (KSHV). This virus can infect and persist in a latent form in cells of the B-cell and endothelial cell lineage and, mainly in immune deficient settings, induce tumors of both cell types. Transcriptional profiling of viral and nonviral B-cell lymphomas and leukemias showed that latently KSHV-infected B-cells are arrested at the penultimate stage of B-cell differentiation into plasma cells (Jenner *et al*., 2003). These tumors are clearly transcriptionally distinct from the CD19 positive B-cells the virus is known to infect (Dittmer *et al*., 1999; Blackbourn *et al*., 2000). This suggests that KSHV, like the related human herpesvirus Epstein Barr Virus (EBV) is able to direct B-cells along differentiation pathways to a B-cell type more suitable for virus latency and possibly lytic replication (Jenner *et al*., 2003). This does not only apply to KSHV and B-cells, as recently KSHV reprogramming of the endothelial transcriptome was demonstrated (Wang *et al*., 2004; Hong *et al*., 2004; Carroll *et al*., 2004) showing that KSHV can infect either blood or lymphatic endothelial cells and drive their gene expression programs to a common intermediary (Wang *et al*., 2004). In both B-cells and endothelial cells, KSHV is thus able

to remodel the host cell transcriptional environment without leading to cell crisis and death. The coordinated molecular mechanisms of such transcriptional remodeling are unknown but suggest that just as viruses helped reveal detailed molecular mechanisms of the cell at the beginning of the molecular biology era, they may also be instrumental in determining authentic transcriptional control networks at a "systems" level of understanding.

The progress in gene expression profiling, however, largely ignores the multicell type, coordinated, and time-dependent dynamic of host and pathogen interaction (Figure 2). The real challenge for the future is to be able to integrate this genome scale complexity into models of how various pathogens survive in the hostile environment of the host and how this maybe exploited to design new strategies and therapies for the treatment of infectious diseases (Fruh *et al*., 2001). Within this setting, it is important to remember that the pathogen is not inert but is also regulating its gene expression to replicate, survive an immune response, and transfer to a new host. Understanding the coordinated, multihost cell choreography of gene

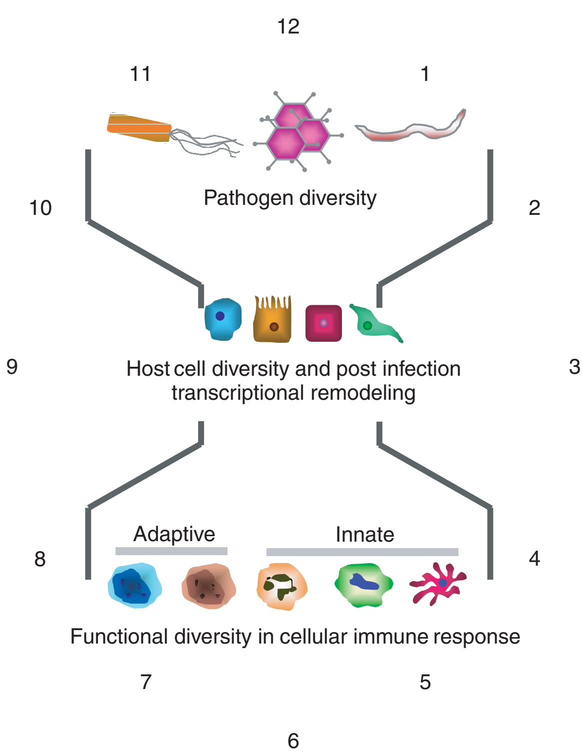

Figure 2 The multicell type, multipathogen context of infectious disease genomics. Different prokaryotic, eukaryotic, and viral microorganisms can interact with or infect probably all cell types of complex multicellular organisms. At the beginning of interaction, the "infection clock" starts, providing the time-dependent context for the remodeling of infected cells gene expression networks. The temporal regulation of both the innate and adaptive arms of the immune system also involves transcriptional remodeling with both conserved and pathogen-specific gene expression programs contributing to a coordinated immune response

expression changes to pathogens represents a challenge to biology at least as great as that posed in understanding developmental biology. With infectious disease accounting for 20–45% of a country's disease burden, and being intimately linked with social, environmental, and economic factors (Weiss and McMichael, 2004), this is a challenge of immense complexity and importance.

Short Specialist Review

Protein microarrays as an emerging tool for proteomics

Ji Qiu and Sam Hanash
Fred Hutchinson Cancer Research Center, Seattle, WA, USA

1. Introduction

Although the concept of a "multianalyte microspot immunoassay" system was first proposed back in late 1980s (Ekins, 1989), it was not until the development and success of DNA microarrays that protein microarrays gained attention, with substantial progress in recent years. Protein microarrays have emerged as a promising approach to meet the pressing need for systematic analysis of thousands of proteins in parallel. Protein microarrays provide a high-throughput, sensitive, and low-volume sample consumption platform for various assays, including the determination of the interactions between proteins and other biomolecules of interest, such as other proteins, antibodies, drugs, and various small ligands. Such assays are essential for basic biological research, for a better understanding of disease processes, and for the identification of novel diagnostic biomarkers and therapeutic targets.

This review addresses protein microarray applications, with a focus on clinical applications, particularly cancer. Additional information about protein microarrays may be found in several review articles that have been published in various journals (Cutler, 2003; Espina *et al*., 2004; Huels *et al*., 2002; Liotta *et al*., 2003; MacBeath, 2002; Templin *et al*., 2002). Furthermore, a recent issue of the journal *Proteomics* (November, 2003) was devoted to protein microarrays and contains both review articles and original research articles.

2. Technical overview – classes and detection methods

From a conceptual point of view, a protein microarray is an array of protein spots on solid supports, typically modified glass slides. Untreated glass slides bind protein poorly, and early on, protein microarrays relied on surface treatments established for DNA microarrays and histological techniques. Heterogeneous or homogeneous protein samples are immobilized on slides through noncovalent ionic interactions with a positively charged surface (such as with polylysine) (Haab *et al*., 2001) or covalent interaction between the primary amines (such as lysine on protein) with the aldehyde group on the slide surface (MacBeath and Schreiber,

2000). However, a need for optimizing the surface chemistries specifically for protein microarrays has been recognized to improve binding capacity, increase signal-to-noise ratio, prevent immobilized proteins from denaturing, and orient proteins properly. Various surfaces using specialized immobilization chemistries have been reported, including the use of nitrocellulose-coated slides to immobilize proteins, with reliance on hydrophobic interactions (Stillman and Tonkinson, 2000), immobilization of biotinylated proteins onto streptavidin-coated surface (Lesaicherre *et al*., 2002), and immobilization of His-tagged proteins onto Ni^{2+}-chelating surfaces (Zhu *et al*., 2001). The experience in the authors' laboratory has shown that glass slides coated with nitrocellulose membrane provided sufficient capacity and a good signal-to-noise ratio (Madoz-Gurpide *et al*., 2001).

There are generally two major classes of protein microarrays (Figure 1). One is intended for protein profiling in which multiple protein capture agents (usually antibodies) are spotted to assay the abundance of corresponding antigens or epitopes in a biological sample such as cell or tissue lysate or biological fluid (Figure 1a–c). Alternatively, multiple biological samples are spotted to assay for proteins that interact with a specific analyte in the biological samples applied to the array (Figure 1d). Another class is intended for functional protein analysis in which large numbers of purified proteins are spotted to study their biochemical properties (Figure 1e–f). Using such arrays, one could efficiently determine potential binding targets of a drug under development or substrates for a kinase of interest in a whole proteome.

The detection of binding in protein microarrays can be based on a sandwich immunoassay in which an immobilized antibody or any other type of capture agent is utilized to capture proteins of interest in a biological sample and a second labeled antibody or capture agent is used to detect and determine the abundance of the protein (Figure 1a). Such an approach, therefore, requires two capture agents that recognize different epitopes on proteins of interest. This dual-capture agent requirement creates constraints for interrogating the abundance of large numbers of proteins simultaneously in a biological sample because it is difficult to have access to high-quality matched antibody pairs.

An alternative to sandwich assays is to label the biological samples before they are hybridized to the arrays. The biological samples can be labeled with either a fluorophore for the direct detection method (Figure 1b) or a hapten tag such as biotin for the indirect detection method (Figure 1c). In the latter case, the arrays are further incubated with fluorophore-conjugated streptavidin. The levels of the proteins in the biological sample, for which corresponding capture agents are arrayed, is determined on the basis of quantifying the amount of fluorophore bound to the immobilized capture agents. Although it is possible to get an accurate measurement of the absolute concentration of proteins of interest in a biological sample using protein microarrays, often the relative concentration between two samples is determined as established for DNA arrays (Schena *et al*., 1996). In one of the earliest studies, 115 antibodies were printed on polylysine-coated slides (Haab *et al*., 2001). Different dilutions of the corresponding 115 antigens mixture were labeled with Cy5 and the reference mixture of the same 115 antigens was labeled with Cy3. Each Cy5-labeled antigen mixture and Cy3-labeled reference were applied to the antibody arrays simultaneously. The ratios of Cy5-to-Cy3 intensity

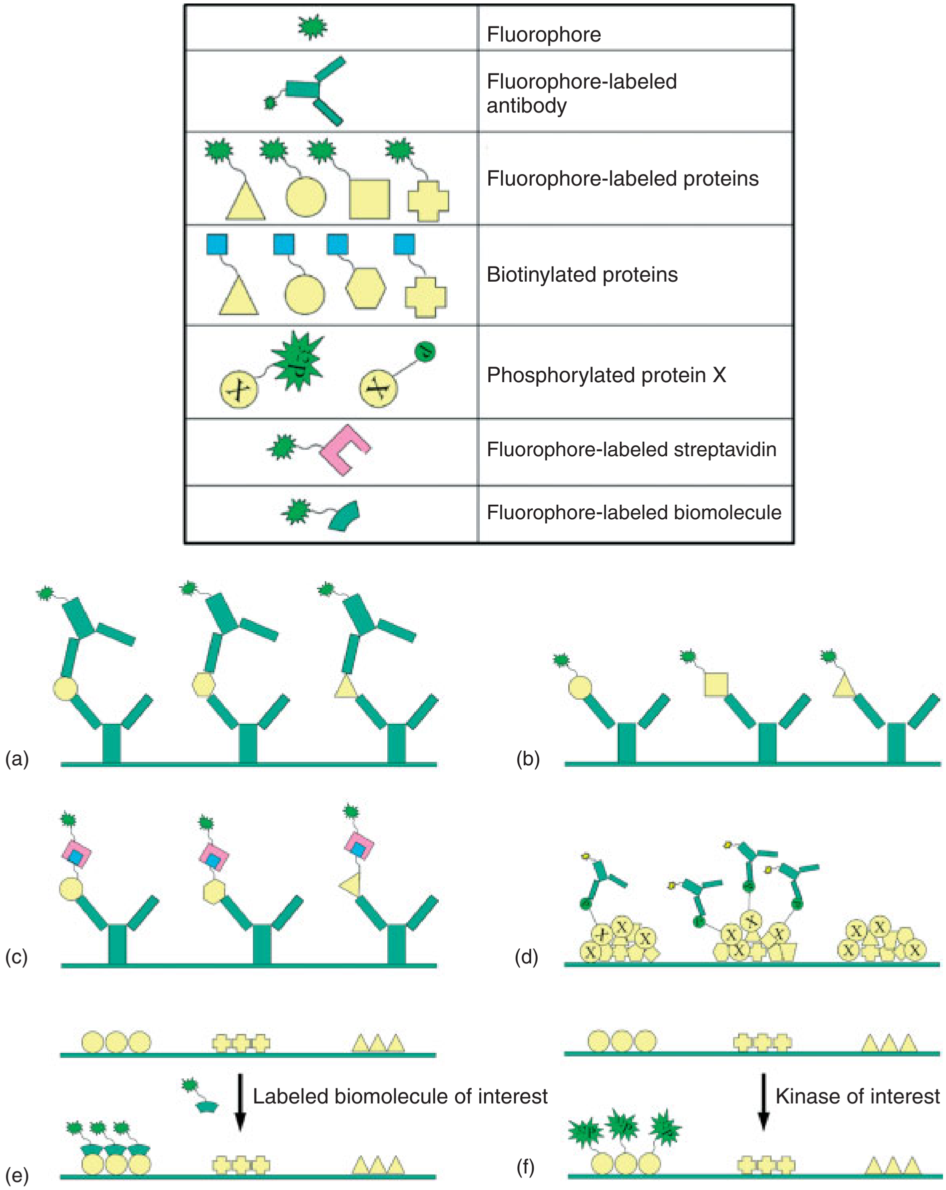

Figure 1 Different classes of protein microarrays. (a–d) Protein profiling microarrays. (a–c) Antibodies are spotted to assay the abundance of respective proteins in biological samples. (a) Sandwich assay detection; (b) direct detection; (c) indirect detection; (d) biological samples are spotted and probed with antiphosphorylated protein X to assay the abundance of phosphorylated protein X in each of the spotted biological samples. (e, f) Two examples of functional protein microarrays. Pure proteins are spotted on protein microarrays. (e) Labeled biomolecules, such as drugs in development or other proteins, are applied to the array to detect potential binding targets of the labeled biomolecules; (f) a kinase of interest is applied to the array to determine potential kinase substrates

at each spot for different antigen dilutions were plotted for each antibody–antigen pair to provide quantitative assessments of antibody–antigen interactions.

The success of protein microarrays relies on sensitive detection methods, as only nanoliter volumes of protein samples are printed for each spot. Tremendous efforts have been made to improve detection sensitivity without loss of resolution or increase in background. Schweitzer *et al*. adopted isothermal rolling-circle amplification (RCA) to protein microarrays to increase sensitivity (Schweitzer *et al*., 2002) and Haab *et al*. successfully implemented this method with the two-color approach (Zhou *et al*., 2004). An alternative is the tyramide signal amplification system that amplifies both fluorescent and chromogenic signals (Paweletz *et al*., 2001).

One concern with the labeling of biological samples is that the labeled biotin or fluorophore might interfere with protein interactions. Methodologies have been developed to detect binding of proteins to the arrays without any pretreatment of the biological samples using either mass spectrometry, surface plasmon resonance (SPR) (Rich *et al*., 2002), or atomic force microscope (AFM) (Lynch *et al*., 2004). These label-free approaches provide more flexibility to experimental design and preserve protein conformation in the biological samples that may be disrupted by labeling. However, these approaches are still at the proof-of-concept stage.

3. Applications

Clinical applications of protein microarrays cover a wide range from their use to detect disease or assess response to therapy based on profiling of biological fluids, to their use for profiling of disease tissue to determine disease subtypes and decide on the most appropriate therapy.

Belov *et al*. utilized a microarray of 60 antibodies directed against a cluster of differentiation (CD) antigens to immunophenotype various types of leukemia (Belov *et al*., 2001; Belov *et al*., 2003). Whole cells were applied to the array to determine expression of CD antigens on the cell surface. Distinctive expression patterns of CD antigens were observed for normal leukocytes and for different types of leukemia. The microarray results compared well with data from established flow cytometry techniques.

As a model to better understand how proteins shape the tissue microenvironment, Knezevic *et al*. analyzed protein expression in tissue derived from squamous cell carcinomas of the oral cavity with an antibody microarray approach (Knezevic *et al*., 2001). Utilizing laser capture microdissection to procure total protein from specific cell populations, they demonstrated that quantitative, and potentially qualitative, differences in expression patterns of multiple proteins within epithelial cells reproducibly correlated with oral cavity tumor progression. Differential expression of multiple proteins was found in stromal cells surrounding and adjacent to regions of diseased epithelium that directly correlated with tumor progression of the epithelium. Most of the proteins identified in both cell types were involved in signal transduction pathways. They hypothesized, therefore, that extensive molecular communications involving complex cellular signaling between epithelium and stroma play a key role in driving oral cavity cancer progression.

Cytokines have become a popular target for analysis using microarrays. In one study, Schweitzer *et al*. printed 51 cytokine antibodies on chemically derivatized glass slides and investigated cytokine secretion from human dendritic cells induced with lipopolysaccharide or tumor-necrosis factor-α (Schweitzer *et al*., 2002). Signal amplification by RCA achieved high specificity, femtomolar sensitivity, 3 log quantitative range, and economy of sample consumption.

There is substantial interest in assembling panels of markers that are simultaneously assayed to allow disease diagnosis or monitoring. Haab *et al*. assembled protein microarrays with antibodies that target 184 distinct proteins to profile prostate cancer serum samples for potential biomarkers (Miller *et al*., 2003). From the profiles of 33 prostate cancer and 20 control serum samples using a two-color fluorescence assay, five proteins (von Willebrand Factor, immunoglobulinM, Alpha1-antichymotrypsin, Villin, and immunoglobulinG) had significantly different levels between the prostate cancer samples and the controls. However, the specificity of any of the reactive proteins for prostate cancer was not assessed. The mining of gene expression data for genes with a distinctive expression pattern in a particular cancer may be a useful source to identify potential serum markers for which antibodies are produced and tested with protein microarrays.

A complementary approach for cancer marker identification consists of the analysis of serum for autoantibodies against tumor proteins. There is increasing evidence for an immune response to cancer in humans, demonstrated in part by the identification of autoantibodies against a number of intracellular and surface antigens detectable in sera from patients with different cancer types (Hanash, 2003). The identification of panels of tumor antigens that elicit an antibody response may have utility in cancer screening, diagnosis, or in establishing prognosis. Such antigens may also have utility in immunotherapy against the disease. There are several approaches for the detection of tumor antigens that induce an immune response. For most antigenic proteins that induce an antibody response in cancer identified using proteomics, posttranslational modifications contributed to the immune response. For example, in a study of lung cancer, sera from 60% of patients with lung adenocarcinoma and 33% of patients with squamous cell lung carcinoma, but none of the noncancer controls, exhibited IgG-based reactivity against proteins identified as glycosylated annexins I and II (Brichory *et al*., 2001). However, these modifications are generally not captured using either recombinant proteins or antibodies that do not distinctly recognize specific forms of a protein. One approach for comprehensive analysis of proteins in their modified forms is to array proteins directly isolated from cells and tissues following protein fractionation schemes. Proteins in reactive fractions are identified by mass spectrometry.

Microarrays that contain natural proteins derived from tumor cells have the potential to substantially accelerate the pace of discovery of tumor antigens to yield a molecular signature for immune responses directed against protein targets in different types of cancer. In a study of lung cancer, protein lysates from the A549 human lung adenocarcinoma cell line were separated into 1840 fractions that were spotted on nitrocellulose-coated slides (Qiu *et al*., 2004). Sera from lung cancer patients and healthy controls were each hybridized to an individual microarray (Figure 2). A total of 63 of the 1840 arrayed fractions demonstrated

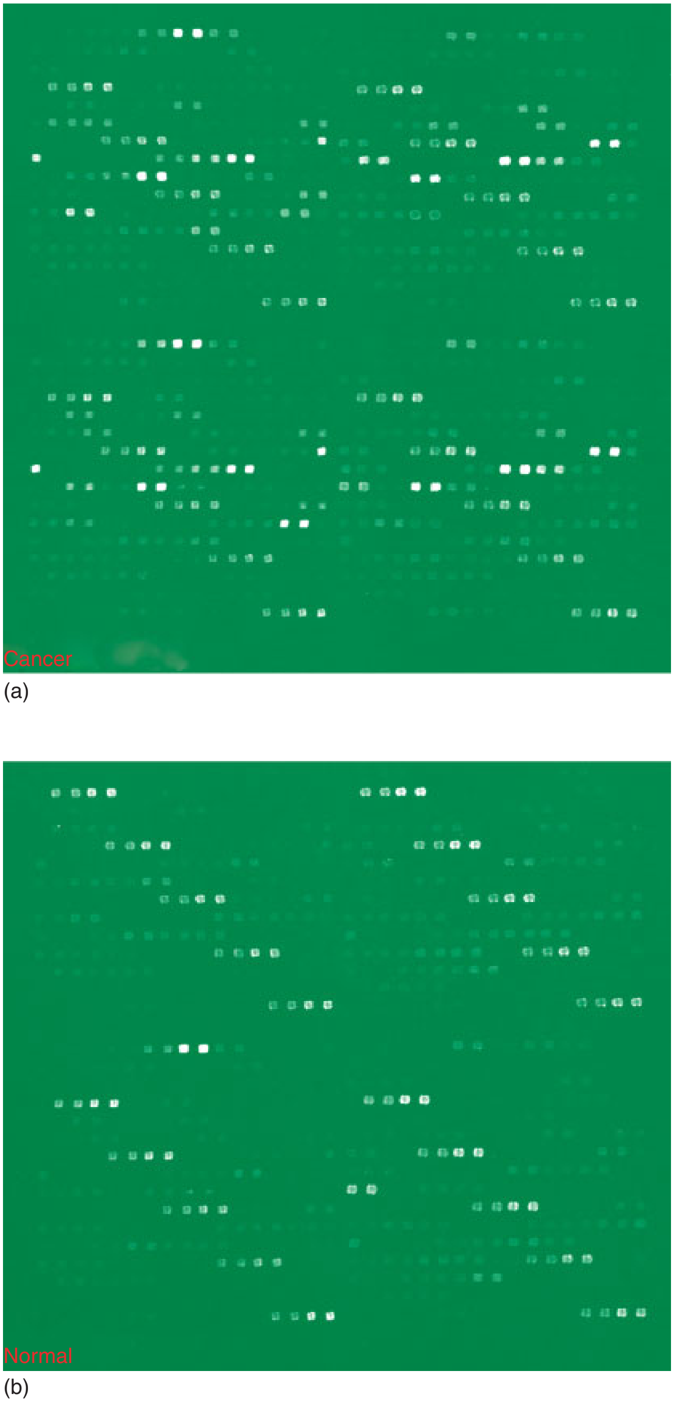

Figure 2 Natural protein microarray images. Whole-cell lysates from A549 lung cancer cell line were separated into 1840 fractions and spotted onto nitrocellulose-coated slides. (a) was hybridized with a lung cancer patient serum sample and (b) a normal serum sample

increased reactivity in cancer patients relative to controls as measured by a rank-based statistic ($p < 0.008$). In a study of colon cancer, microarrays printed with 1760 distinct protein fractions, prepared from the LoVo colon adenocarcinoma cell line, were hybridized with individual sera (Nam *et al*., 2003). A fraction that exhibited IgG-based reactivity with 9/15 colon cancer sera was found to contain Ubiquitin C-terminal hydrolase L3 (UCH-L3) by tandem mass spectrometry (ESI-Q-TOF). The highest levels of UCH-L3 mRNA among the 329 tumors of different types analyzed by DNA microarrays were found in colon tumors. Independent validation by Western blotting demonstrated that UCH-L3 antibodies existed in 19/43 sera from patients with colon cancer, and in 0/54 sera from subjects with lung cancer, colon adenoma or otherwise healthy. These data point to the utility of microarrays printed with natural proteins for the identification of tumor antigens that have induced an antibody response in patients with specific cancers.

Another clinically relevant application of protein microarrays is the identification of proteins that induce an antibody response in autoimmune disorders (Hueber *et al*., 2002; Robinson *et al*., 2002). Microarrays were produced by attaching several hundred proteins and peptides to the surface of derivatized glass slides. Arrays were incubated with patient sera, and fluorescent labels were used to detect autoantibody binding to specific proteins in autoimmune diseases, including systemic lupus erythematosus and rheumatoid arthritis. In a more recent study (Robinson *et al*., 2003), a "myelin proteome" microarray was developed to profile the evolution of autoantibody responses in experimental autoimmune encephalomyelitis, a model for multiple sclerosis. Increased diversity of autoantibody responses predicted a more severe clinical course. Chronic experimental autoimmune encephalomyelitis was associated with previously undescribed extensive intra- and intermolecular epitope spreading of autoreactive B-cell responses. Proteomic monitoring of autoantibody responses provided a useful approach to monitor autoimmune disease and to develop and tailor disease- and patient-specific tolerizing DNA vaccines. Protein microarrays have also been used to predict resistance or susceptibility to future autoimmune disease from the present antoantibody repertoire (Quintana *et al*., 2004). Reaction patterns of mouse sera obtained before cyclophosphamide treatment, with 27 different antigens (out of 266 antigens printed on the microarrays), could predict whether a particular mouse would develop cyclophosphamide-accelerated diabetes.

Unlike DNA microarrays, which provide only one measure of gene expression, namely RNA levels, many different features of proteins may be addressed by different types of protein microarrays, including, on the one hand, determination of protein abundance in biological samples, and on the other, determination of their functional states, as may be deduced, for example, from their extent of phosphorylation. Many cellular processes are regulated by reversible protein phosphorylation (Cohen, 2002; Eckhart *et al*., 1979). Genetic changes related to oncogenes or tumor suppressor genes that lead to cancer development also result in alterations of protein phosphorylation patterns (Vogelstein and Kinzler, 2004). A systematic profiling of functional states of proteins involved in signal transduction pathway provides insight into disease development and treatment. The development of reagents that allow assessment of protein modification such as phosphorylation, glycosylation, or other functionally relevant protein changes has substantial utility

for clinical investigations. Therefore, protein microarrays using antibodies specific to phosphorylated protein have been the focus of a number of recent studies.

Paweletz *et al*. arrayed whole-protein lysates prepared from multiple microdissected cancer samples (Paweletz *et al*., 2001). Each array was interrogated with a single antibody to determine the level or posttranslational modification of a particular protein in the arrayed lysates. A high degree of sensitivity, precision, and linearity was demonstrated, making it possible to quantify the phosphorylation state of signaling proteins in human tissue lysates. Using this approach, Paweletz *et al*. analyzed pro-survival checkpoint proteins at the transition stage from patient-matched histologically normal prostate epithelium to prostate intraepithelial neoplasia and to invasive prostate cancer. Cancer progression was associated with increased phosphorylation of Akt, suppression of apoptosis pathways, as well as decreased phosphorylation of ERK. At the transition from histologically normal epithelium to intraepithelial neoplasia, a statistically significant increase in phosphorylated Akt and a concomitant suppression of downstream apoptosis pathways preceding the transition into invasive carcinoma were observed.

Nielsen *et al*. profiled the ErbB receptor typrosine kinase in human tumor cell lines (Nielsen *et al*., 2003). They demonstrated that antibody arrays accurately profiled the functional state of the ErbB signaling pathway, not just ErbB abundance. Data obtained from microarrays correlated very well with data obtained using traditional approaches. Only a handful of antibodies were used for this prototype study. Scaled up studies based on the availability of capture agents would permit the systematic analysis of cellular signal transduction networks in cancer.

Antibody microarrays with a relatively limited content, compared to DNA microarrays, have become commercially available. For example, the BD Clontech Ab Microarray 500 consists of 500 distinct antibodies that detect a variety of human proteins either in circulation or in cell and tissue extracts. The antibody set targets a broad range of functional classes involved in signal transduction, cell growth and proliferation, apoptosis, inflammation, and the immune response. A complete list of the antibodies on this array is available at **http://bioinfo2.clontech.com/abinfo/abinfo/array-list-action.do**. Other commercially available antibody microarrays that interrogate a more limited or a particular class of proteins are also available. The content and variety of commercially available microarrays are likely to continue to expand. A potential limiting factor for the use of commercial microarrays is their cost.

Traditionally, protein biochemical properties are assayed one at a time. However, protein microarrays provide a platform that protein functions can be assayed at proteome scale with the advantages of low reagent consumption, rapid interpretation of results, and the ability to easily control experimental conditions. For this application, microarrays are constructed with purified recombinant proteins encoded by the whole proteome or subproteome of interest and are used to analyze protein biochemical activities, protein–protein interactions, or protein–small molecule interactions, as has been successfully demonstrated with the yeast whole-proteome microarray (Michaud *et al*., 2003; Zhu *et al*., 2001; Zhu *et al*., 2000). For reviews on functional protein microarrays, see Schweitzer *et al*. (2003) and Wilson and Nock (2002).

4. Challenges and perspectives

There is increased appreciation of the merits of protein microarrays given their multiplexing nature and high sensitivity. The number of applications using protein microarrays is expanding rapidly, especially in clinical research in view of the limited amount of samples available from human subjects. However, substantial challenges still remain, both for strategies that rely on arrayed capture agents and for strategies that rely on arrayed proteins. Currently, antibodies are widely used as the capture agents for protein microarrays because they can provide excellent specificity. However, the limited availability of such antibodies with the requisite specificity limits the coverage that can be achieved at the present time with protein microarrays. The development of antibodies is a laborious and costly process. The challenge is to devise strategies to produce highly specific antibodies at a proteome scale. The compelling need for capture agents with the prerequisite specificity has led numerous biotechnology companies and research labs to devise novel strategies to replace antibodies that include aptamers (SomaLogic, **http://www.somalogic.com/**), phage display (Dyax, **http://www.dyax.com**), ribozymes (Archemix, **http://www.archemix.com/**), and partial-molecule imprints (Aspira Biosystems, **http://www.aspirabio.com**). Additionally, in principle, when used in combination, some combinatorial strategies are being considered in which a limited repertoire of capture agents that target epitopes shared by sets of proteins such as protein families may be devised that could provide proteome-scale coverage. Such strategies may yield distinctive patterns of reactivity that may be clinically or biologically informative but would have difficulties in identifying the specific reactive protein(s).

For strategies that rely on arrayed proteins, there is a substantial challenge in producing proteins at a proteome scale. *Escherichia coli* has been the dominant expression system to produce recombinant proteins for functional protein microarrays. Some use has been made of synthetic peptides, for limited applications in which protein conformation is not of concern, such as linear epitope mapping (Pellois *et al*., 2002; Reimer *et al*., 2002). Eukaryotic proteins expressed in *E. coli* usually fail to fold into their native conformations and be posttranslationally modified, as occurs in the tissues in which they are originally expressed. Therefore, data obtained from microarrays arrayed with bacterially expressed recombinant proteins are not fully informative. Consequently, there is a substantial need to develop alternative expression systems to produce pure proteins with proper folding and posttranslational modification. High-throughput protein production in some eukaryotic expression systems that rely on yeast, insect, or mammalian cells is currently being explored (Braun and LaBaer, 2003; Gilbert *et al*., 2004).

It is expected that the reach of protein microarrays will continue to expand gradually as resources are developed. Eventually, the use of such arrays will become widespread, thus contributing substantially to proteome research and diagnostic use.

Short Specialist Review

Tissue microarrays

Ronald Simon, Martina Mirlacher and Guido Sauter
University Medical Center Hamburg-Eppendorf, Hamburg, Germany

1. Introduction

A variety of powerful high-throughput technologies are available for the identification of potentially relevant genes in individual tissue samples. These tools generally identify more interesting genes than the resources that are available for their further analysis. In situ analyses methods are optimally suited for studying gene alterations. Technologies such as immunohistochemistry (IHC), fluorescence in situ hybridization (FISH), and to some extent also RNA in situ hybridization (RNA ISH) allow a cellular and subcellular localization of the gene product of interest and a clear distinction between diseased and nondiseased cells. However, traditional slide-by-slide analysis cannot match the speed of modern high-throughput target-identification technologies. Tissue microarrays (TMAs) permit in situ analysis of hundreds of tissue samples on one microscope glass slide. Since studies have shown that minute tissue samples as small as 0.6 mm in diameter are sufficiently representative of their donor tissues (reviewed in Sauter *et al*., 2003), TMAs have become a widely used research tool.

2. TMA technology

Hundreds of cylindrical samples measuring up to 4 mm (usually 0.6 mm) in diameter are removed from formalin-fixed or frozen tissues and placed into one recipient block (Kononen *et al*., 1998). Simple commercial or homemade arrayers can be used for this purpose. Sections from such TMA blocks containing hundreds of different tissues are then placed on a glass slide. All methods for in situ tissue analysis can be performed on TMAs using similar protocols as for conventional large sections (Figure 1).

3. TMA applications

After its initial description in 1998 (Kononen *et al*., 1998), TMAs have become widely used in recent years. More than 150 publications published in 2003 have utilized TMAs. Some of the most powerful applications of TMAs are described below.

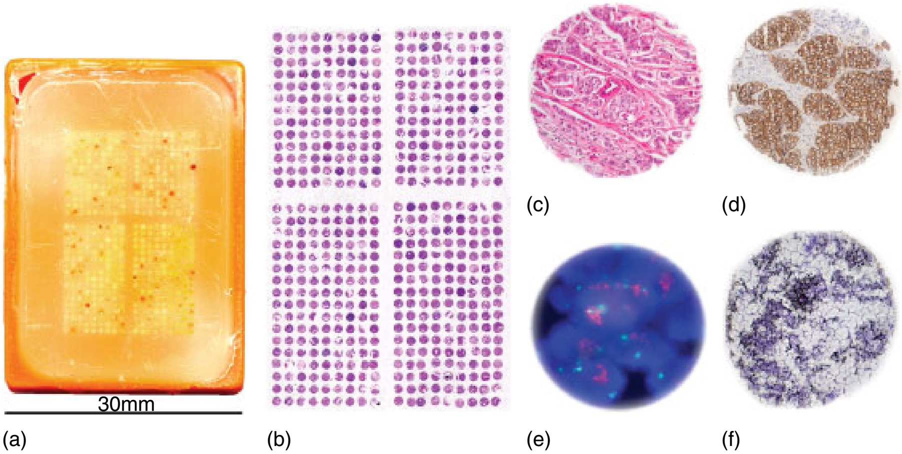

Figure 1 Tissue microarrays and TMA applications. (a) TMA block; (b) hematoxylin and Eosin (H&E)-stained section (5 µm) of the TMA; (c) magnification of a H&E-stained tissue spot (diameter 0.6 mm); (d) immunohistochemistry of a breast cancer tissue spot. Brownish membranous staining indicates strong expression of the Her2 receptor protein. (e) FISH analysis. Magnification (1000x) of cell nuclei (blue staining) showing two green signals corresponding to the centromere of chromosome 17 and multiple red signals indicating *Her2* gene amplification. (f) RNA in situ hybridization on a TMA spot from frozen tissue using an radioactively labeled oligonucleotide probe

3.1. TMAs for molecular epidemiology

Data on the expression of a given gene are often available from the literature. However, examples of extensively analyzed genes suggest that published data often lack practical value. For example, *HER2*, the target gene for Trastuzumab (Herceptin) has been analyzed in thousands of publications. Yet, the data are highly controversial. Published expression frequencies range from <10 to >90% for many important tumor types (reviewed in Sauter *et al*., 2003). The paramount impact of experimental parameters such as antibody selection, IHC protocol, tissue characteristics, and scoring criteria on the results of IHC analyses greatly reduce the comparability of IHC data derived from different groups. TMAs containing samples from all different tumor types make it possible to analyze a gene of interest under fully standardized conditions in one experiment. For example, we used a set of TMAs containing more than 3500 different samples from more than 120 different tumor categories to investigate target genes for established drug targets such as KIT/CD117 (Imatinib; Glivec) (Went *et al*., 2004) or epidermal growth factor (EGFR) (Tarceva, Iressa, Cetuximab, Erbitux) (Sauter *et al*., 2003). Such studies often show expression of a target gene in a wide variety of tumor entities. The analysis of a representative number of cases from various tumor types typically results in a representative ranking list of marker expression in different tumor entities (Sauter *et al*., 2003).

3.2. TMAs for prognosis evaluation

TMAs containing a large number of samples from one tumor type with attached clinico-pathological information allow an estimation of the biological importance

of a gene alteration. Associations with advanced stage, high grade, presence of metastases, or poor clinical outcome argue for a role in tumor progression. TMAs are highly efficient in identifying associations between molecular features and prognosis. For example, significant associations were found between estrogen or progesteron expression (Torhorst *et al*., 2001) or HER2 alterations (Barlund *et al*., 2000) and survival in breast cancer patients, between vimentin expression and prognosis in kidney cancer (Moch *et al*., 1999), and between Ki67 labeling index and prognosis in urinary bladder cancer (Nocito *et al*., 2001), soft tissue sarcoma (Hoos *et al*., 2001a), or Hurthle cell carcinoma (Hoos *et al*., 2002).

3.3. TMAs for normal tissue evaluation

The expression pattern of genes of interest in normal tissues is often important. Often it allows conclusions on the potential biological role of a gene product. Normal tissue analysis is critically important for potential drug targets. Expression of a target gene in important normal cell types may predict the site of potential side effects. Cell type–specific expression analysis would not be possible if other methods than in situ techniques were used. For example, EpCam, a target for several anticancer therapies, is expressed in bile ducts of the liver. Since bile ducts constitutes are a very small (<1%) component of the liver, EpCam analyses by non–in situ techniques would suggest either no or low expression in liver (Figure 2). IHC analysis, however, reveals high EpCam levels in a small but vital liver compartment.

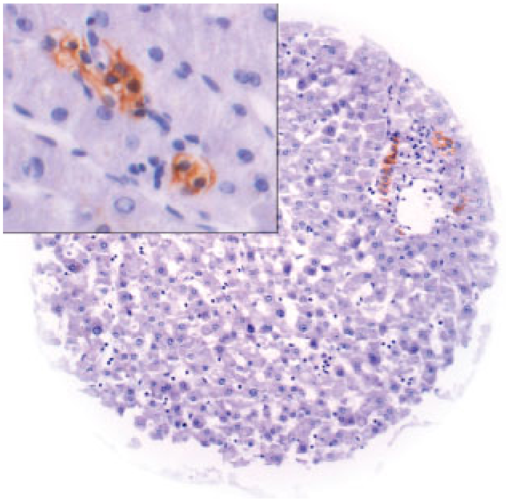

Figure 2 EpCam expression in a tissue spot from normal liver. Inset: 1000x magnification. EpCam expression if confined to small areas of bile ducts. A similar staining intensity, however, can be seen as well in cancer cells. This emphasizes the importance of in situ analyses for normal tissue evaluation. The use of disaggregated tissue for such an expression comparison (like Northern or Western blots) would suggest a negligible low expression level in normal liver

3.4. *Important technical aspects*

Although the technology is simple and easily applicable, some aspects of TMAs are controversially discussed and others are underestimated. Understanding the impact of tissue heterogeneity, the potential for automation, and the importance of pathology expertise is particularly important for the successful use of TMAs.

4. Tissue heterogeneity

The utility of TMAs for reliably finding associations between molecular and clinicopathological features is the breakthrough discovery of the TMA field. Placing multiple tissues into one paraffin block has been described before (Wan *et al*., 1987). At this time, it was found that molecular analysis of small tissue samples would be insufficient for the identification of clinically relevant information. Technical improvements, therefore, aimed at the deposition of as large as possible tissues on multitissue blocks (Battifora, 1986). Remarkably, all studies comparing molecular features obtained on TMAs (with a spot diameter of 0.6 mm) with clinical or pathological data found the expected associations if these were previously well established (reviewed in Sauter *et al*., 2003). Results of these studies considerably weaken the practical importance of studies showing an increasing concordance between TMA data and corresponding large section results if 3–4 tissue samples are analyzed per tumor (Rubin *et al*., 2002; Engellau *et al*., 2001; Camp *et al*., 2000; Fernebro *et al*., 2002; Hoos *et al*., 2001b). It is obvious that TMA results will match large section results more closely if the highest possible number of cores per tumor block is analyzed. However, as shown in a p53 analysis in breast cancer, this has also disadvantages. Notably, the risk of false positivity is also increasing with the size of analyzed tissue. Torhorst *et al*. (2001) found p53 positivity to be prognostically relevant in four independent TMAs composed of one core each of >500 breast cancers but not in corresponding large sections. The use of TMAs containing only one core per tumor is therefore recommended for the vast majority of applications.

5. Pathology expertise and automation

Although TMA technology is often discussed in the context of other array techniques such as DNA or protein arrays, for which array construction, analysis, and data recording can easily be automated, the TMA method is fundamentally different. TMAs represent the ultimate miniaturization of molecular pathology and share the inherent strengths and limitations of pathology analyses. The level of pathology expertise is most decisive for the success of TMA studies, while classical array tools like automation are less relevant. Automated TMA manufacturing lacks importance, because sufficiently large ready-to-use "tissue libraries" are lacking.

Classical pathology skills are critical for the classification of arrayed tissues, experimental design, and staining interpretation. More than 100 studies can be

based on one TMA block. As the molecular data will be compared with pathological information, the quality of "basic pathology data" is of highest importance. The difficulties related to the development of an adequate IHC protocol are greatly underestimated. Nonspecific positivity is a frequent problem and requires the use of multiple controls. A significant fraction of antibodies cannot be optimized for use on tissue sections. In general, IHC staining results are greatly dependent on antibody selection, antigen retrieval strategy, staining protocol, and on minor variables such as the section age (Mirlacher *et al*., 2004). For example, the use of three different antibodies for EGFR resulted – after state-of-the-art protocol development – in an up to fivefold difference in the rate of positivity (Sauter *et al*., 2003).

These inherent difficulties reduce the importance of automated TMA analyses. Although studies have demonstrated the feasibility of automated quantitation of brightfield or fluorescence signals on TMAs, automated systems have limited capability for recognition of staining artifacts, necrotic, crushed or damaged tissue elements, or for distinction of neoplastic versus nonneoplastic cells. Nevertheless, modern imaging tools have high value for image documentation and preliminary screening of staining results in a high-throughput scale. At the same time, manual (visual) analysis of the TMA staining by an experienced pathologist provides the greatest level of reading precision and will remain the gold standard for TMA staining interpretation. Attempts to improve automated TMA analysis are paralleled by an increased use of lysate arrays composed of protein extracts from tumor tissues (Nath and Chilkoti, 2003; Nishizuka *et al*., 2003). These are spotted on glass slides in a DNA array-like manner and can be analyzed with the same software used for DNA arrays. If morphologic information is not needed, lysate arrays may represent a better option than complicated and expensive systems for automated TMA analysis.

The use of external controls in microarray experiments

Joop M.L.M. van Helvoort, Dik van Leenen and Frank C.P. Holstege

University Medical Center Utrecht, Utrecht, The Netherlands

1. Introduction

Expression profiling using DNA microarrays results in either ratios of mRNA expression levels or in an absolute measurement that is correlated to the expression level. This chapter deals with how the accuracy of such experiments can best be evaluated using external experimental controls where the accuracy refers to how close the observed value is to the real biological value. Generally speaking, there are at least two different scenarios that require a good assessment of microarray accuracy. The first scenario is determining the accuracy in order to decide which technology works best. For example, do the microarrays from one particular supplier work as well as those from other sources? Or, how will various sample handling and labeling strategies affect the accuracy of a microarray experiment? The question of accuracy can of course be posed for the refinement of every step of the experimental procedure or production process, whether it is the use of different oligomer lengths for manufacture, assessment of different hybridization protocols, or even assessment of different data-processing strategies. A second scenario that requires assessment of accuracy is at the level of every individual assay, in order to check that each hybridization gives results of similar accuracy, that is, after the optimization process.

Despite the obvious importance in determining accuracy and the great interest in microarray technology, limited information is available concerning systematic analysis of microarray accuracy during technique optimization or for collections of individual experiments. One method that may be chosen to optimize protocols is to measure and increase signal intensity. The assumption made here is that increased signal to noise will yield more accurate experiments. For instance, the Tumor Analysis Best Practices Working Group states that the percentage of present calls on the Affymetrix platform is an important QC criterion (Hoffman *et al*., 2004). Anecdotally, we know that increase in fluorescent signals have often been used as the main criteria for technique optimization. It should be noted, however, that in particular, on the other array platforms, an increase in signal may in fact be the result of an increase in aspecific target binding, for example, due to increased

cross-hybridization. It should be further noted that signal saturation can lead to loss of dynamic range and the inability of microarrays to measure real changes in expression levels.

A second method to evaluate if a technique has been fully optimized is to compare a new method with the one that has already been widely accepted, using a correlation coefficient to determine how similar the results of the two methods are. However, a correlation coefficient only gives information on how closely the two protocols behave and does not give any information on the accuracy of either one. A high correlation may mean that the compared technologies simply suffer from the same systematic errors. Whether ratios or absolute intensities are being compared, a low correlation still begs the question of which technique is the most accurate. Using correlation coefficients of intensities in order to monitor and improve reproducibility, for example between two channels, can also suffer from the drawback that the technology is being optimized for yielding identical results rather than accurately reporting differences in expression.

A third method for evaluation is to use an established cell line or tissue culture experiment that reproducibly shows differences that can be verified with other techniques such as Northern blotting or quantitative RT-PCR. This assumes that these alternate techniques accurately report differences in expression. Nevertheless, differential cell culture experiments are a good method because this does involve optimization of reporting established differences in expression, which is the goal of most microarray experiments. One disadvantage is that verification and optimization is driven by the differences reported in the microarray experiment. There is no test for false-negatives, unless RT-PCR, for example, is carried out on many thousands of genes not reported as differentially expressed by the microarray experiment. A second drawback is that this does not lend itself to the routine assessment of every single microarray experiment carried out after optimization. This is especially important for projects that require reproducible accuracy across many hybridizations or if collections of microarray experiments are to be compared with each other.

In this chapter, we discuss a fourth approach for optimizing nearly any aspect of microarray technology that does not suffer from the disadvantages outlined above and that also lends itself for reporting accuracy within every subsequent microarray experiment after optimization. This approach is based on the use of external controls, also known as spikes, spike-in controls, exogenous controls, or external standards. We describe what external controls are, how they may contribute toward systematic analyses of accuracy, and how such controls should be implemented. Other uses of external controls such as normalization, determining sensitivity, and reporting absolute mRNA copies per cell are also discussed.

2. External controls

External controls are in vitro synthesized RNA molecules that can be exogenously added to the RNA sample that is to be assayed. The distinct advantage of control RNAs is that there is complete control over their use, in particular, over the amount that is added to samples, which makes such controls extremely

versatile. Although external controls have been introduced and used sporadically at quite early stages in microarray technology (Holstege *et al*., 1998; Lockhart *et al*., 1996), it is apparent that their virtue is only starting to be fully recognized through the increased demand for the standardization of microarray experiments. A good example is the External RNA Controls Consortium initiative (ERCC, **http://www.ctsl.nist.gov/biotech/workshops/ERCC2003/**), which is presently being launched to supply the microarray community with standard external controls that are "platform-independent control materials needed for the performance evaluation of reproducibility, sensitivity, and robustness in gene expression analysis."

When external controls are added in fixed amounts to experimental RNA samples, they can be used to test how well their representation within each sample, or their ratios between two samples, are determined by the microarray experiment. For example, they may be added at fixed ratios in any quantity between two otherwise identical RNA samples in order to mimic differences in mRNA expression for a small number of genes. In this case, the microarray features representing the external controls are the only features on the microarray that should be reporting differences in RNA levels. Different control RNAs can also be added to RNA samples at defined picomolar amounts in order to test the sensitivity of an experiment by covering the entire range of possible mRNA expression values (Lockhart *et al*., 1996; Ramakrishnan *et al*., 2002). A combination of different ratios and different quantities is especially useful, because experiments can be evaluated on the basis of sensitivity as well as accuracy in reproducing the actual spiked ratios (Badiee *et al*., 2003; Hughes *et al*., 2001; Kane *et al*., 2000; Richter *et al*., 2002; Wang *et al*., 2003).

The accuracy of a microarray experiment is affected by the individual steps that make up such an experiment: RNA isolation, target synthesis and labeling, hybridization, and image and data analysis. The external controls can be used to determine how the accuracy is influenced during a microarray experiment from the moment they have been added. To give an example, when the controls are labeled separately and added just before hybridization, the accuracy of hybridization and subsequent steps can be determined (Dudley *et al*., 2002; Hughes *et al*., 2001; Lockhart *et al*., 1996). To test the effect of the complete experimental procedure on accuracy, the external controls could also be added to the lysis buffer of the RNA isolation method or as encapsulated RNA prior to RNA isolation, as suggested by the ERCC.

When data from individual hybridization assays are to be compared, any differences introduced by variation in the experimental procedure have to be countered by normalization. In the vast majority of publications involving microarrays, the data of the gene-specific features of a microarray are used for normalization because these data cover the whole array layout and the complete intensity range. However, using gene-specific features has the disadvantage that normalized differences in gene expression will always be balanced. That is, approximately as many genes will be downregulated as upregulated (Figure 1a and c) (Van De Peppel *et al*., 2003) because the underlying assumption is that gene expression, on average, does not change between samples. This does not necessarily represent what is really taking place in the biological samples, especially

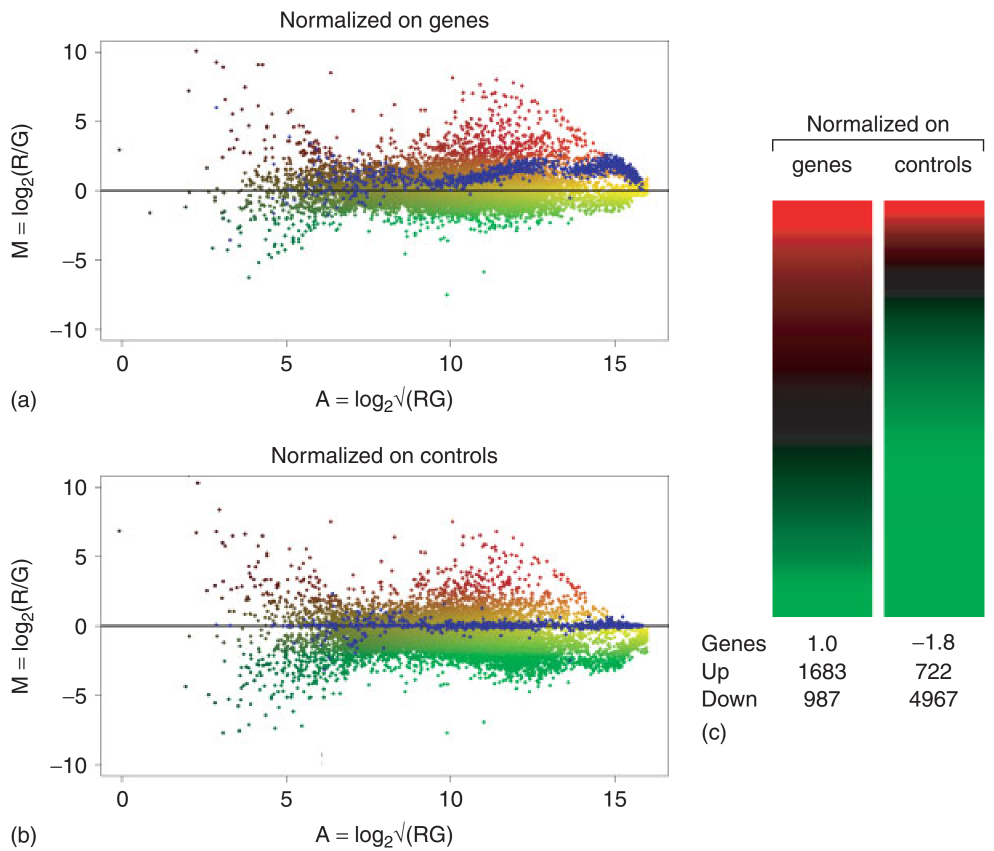

Figure 1 Use of external controls in normalization. Yeast cells were either grown exponentially in log phase or cultured during stationary phase. Nine different external controls were added to the total RNA of mid-log phase and stationary phase samples in a 1:1 ratio. cDNA of the stationary phase sample was Cy5-labeled and cDNA of the log-phase sample was Cy3-labeled. Hybridization was performed on in-house spotted yeast slides. (a) and (b) are MA scatterplots after lowess normalization on genes (a) or controls (b). (c) illustrates the difference between the two normalization strategies in the amount of genes that are up- or downregulated. After normalization on genes, a similar number of genes is up- as is downregulated (a). On the other hand, after normalization on controls, most genes show decreased expression (b). (Reproduced with permission from Van de Peppel *et al*. (2003). © EMBO)

when global changes in gene expression are expected. In other words, the accuracy of a measurement can be severely affected, when genes are used for normalization. However, external controls avoid these limitations and can be used to determine global or unbalanced changes. An example of global changes in gene expression is the comparison of exponentially grown cells with cells in stationary phase, where mRNA synthesis is expected to be decreased. In spite of this reduction in mRNA levels, fixed amounts of labeled material that corresponds to equal amounts of mRNA are applied on a microarray for both exponentially grown as well as stationary phase cells. By adding an identical amount of external control RNA to the same amount of total RNA, the external controls can be used to normalize for equal amounts of total RNA (Figure 1b and c) (Van De Peppel *et al*., 2003).

Another experimental situation that may require external control normalization is the use of microarrays carrying a relatively small number of features, such as those dedicated to a specific biological process or type of genes. Here, changes in expression may be unbalanced because of the preselection of genes as these arrays are typically designed to use genes that are consistently differentially expressed under the experimental condition under study.

It should be noted that the use of external controls does not limit the approaches one can use to normalize data; external controls have been used for total intensity normalization (Holstege *et al*., 1998; Kane *et al*., 2000) but can also be used in local intensity–dependent normalization (e.g., lowess, Yang *et al*., 2002), provided that a number of control RNAs are used with a range of spike-in concentrations.

The amount of external controls that is added is normally expressed as a molar quantity or as picograms per micrograms of total RNA or mRNA. Although the representation of external controls as copy number per cell is informative for the sensitivity in a microarray experiment, the quantitative conversion of the amount of external controls to a copy number per cell is not trivial. To express the sensitivity and accuracy of a method as mRNA copy numbers per cell (e.g., Kane *et al*., 2000), several assumptions have to made. The important variables used in various publications to calculate the copy number per cell are average transcript length (for humans, this has varied between 1000 and 2700 bp, Hughes *et al*., 2001, **http://www.ncbi.nlm.nih.gov/Web/Newsltr/spring03.human.html**), total RNA per cell (e.g., 20 pg, Kane *et al*., 2000), total number of polyA transcripts per cell (e.g., 100 000 or 360 000, Hughes *et al*., 2001; Kane *et al*., 2000), and percentage of mRNA within the total RNA used. The simple formula below can be used to estimate the spiked-in equivalent, expressed in transcripts per cell, when a known amount of external control RNA has been added to total RNA.

$$transcript\ \ per\ \ cell = \frac{Y(g)}{X(g)} \times \frac{total\ \ transcripts\ \ per\ \ cell}{perc.of\ \ mRNA\ \ in\ \ total\ \ RNA} \times 100 \qquad (1)$$

where Y is the amount of external control in grams and X is the amount of total RNA in grams.

3. Requirements for external controls

In view of the fact that external controls are used to monitor changes in sample RNA, it is imperative that external control RNA behaves similarly to the sample mRNA and, consequently, both should have the same physical properties, including similar lengths and GC content. When used for eukaryotic samples, external controls should also have a polyA tail, preferably of the same length as for eukaryotic mRNA. This is important as the length of the polyA tail can affect the behavior of sample mRNA and external control RNA in at least four ways. First, because a polyA tail is a region of low complexity, the risk of cross-hybridization is increased if the polyA tail is also included in the probe. Second, when modified (d)UTPs are used for labeling, they will be incorporated at the position of the polyA tail. A difference in the length of the polyA tail will result in a different

number of labeled (d)UTPs at this position between control RNA and sample mRNA. This can cause a discrepancy in the way the signal intensity corresponds to the number of transcripts for similar amounts of control mRNA and sample mRNA. Third, when labeled nucleotides are in close proximity to one another in the polyA tail, in particular at this position, the risk for quenching of fluorescence will increase with higher labeling percentages ('t Hoen *et al*., 2003). The use of a two nucleoside anchored primer at the 5′ end of the polyA tail or random primers in target synthesis can circumvent these problems. Fourth, many RNA amplification and labeling protocols rely on priming from the polyA tail and it is important that the controls and the experimental RNA have the same priming efficiencies.

4. Concluding remarks

As more and more laboratories will become involved in microarray technology, the demand for a format that can be used as an aid in data comparison will become greater. The use of external controls, especially when standardized, is extremely helpful in evaluating the diversity of data that is being generated. Eventually, these external controls will enable scientists to perform more accurate analyses of microarray experiments from different sources.

SAGE

Seth Blackshaw
Johns Hopkins University School of Medicine, Baltimore, MD, USA

1. Introduction

Serial analysis of gene expression (SAGE) shares much in common with other digital gene expression technologies such as expressed sequence tag (EST) (*see* Article 78, **What is an EST?**, Volume 4) sequencing and massively parallel signature sequencing (MPSS). These techniques all aim to comprehensively profile gene expression by obtaining short stretches of DNA sequence from randomly selected cDNAs in a sample of interest. As when conducting an opinion poll, the more cDNAs that are sampled, the more accurate and comprehensive is the resulting expression profile. SAGE distinguishes itself from other technologies by the cloning and sequencing of multiple concatenated sequence tags – short DNA sequences obtained from a defined point within each cDNA that are long enough to uniquely identify each transcript (Velculescu *et al*., 1995; Saha *et al*., 2002).

2. How is SAGE performed?

mRNA molecules from a sample of interest are bound at their 3′ ends using magnetic beads conjugated to oligo (dT), and first- and second-strand cDNA is synthesized. The sample is then digested to completion with a four-base cutter restriction enzyme (usually NlaIII by convention, although any enzyme can be used) (see Figure 1, Step 1). All sequences that lie 5′ of the 3′-most NlaIII site is thus lost, and this NlaIII site will define the position of the sequence tag.

A linker containing both a PCR primer and a type IIS restriction site is then ligated to the 5′ end of the cDNA (Figure 1, Step 2). The sample is typically divided into two at this point, with linkers that differ only in the PCR primer sequence being used. The sample is then digested with the type IIS enzyme whose site is encoded in the linker. Depending on the enzyme used, this enzyme cleaves within the cDNA anywhere from 10 to 22 bp 3′ of the NlaIII site, generating the SAGE tag for that particular transcript. Cleaved tags are typically blunt-ended, after which cleaved tags ligated to the two sets of linkers are combined, ligated together to form ditags, and amplified by PCR (Figure 1, Step 3).

Ditags are then recleaved with NlaIII, gel purified, ligated to form concatemers, and subcloned into plasmid vectors to form a SAGE library. Individual clones are

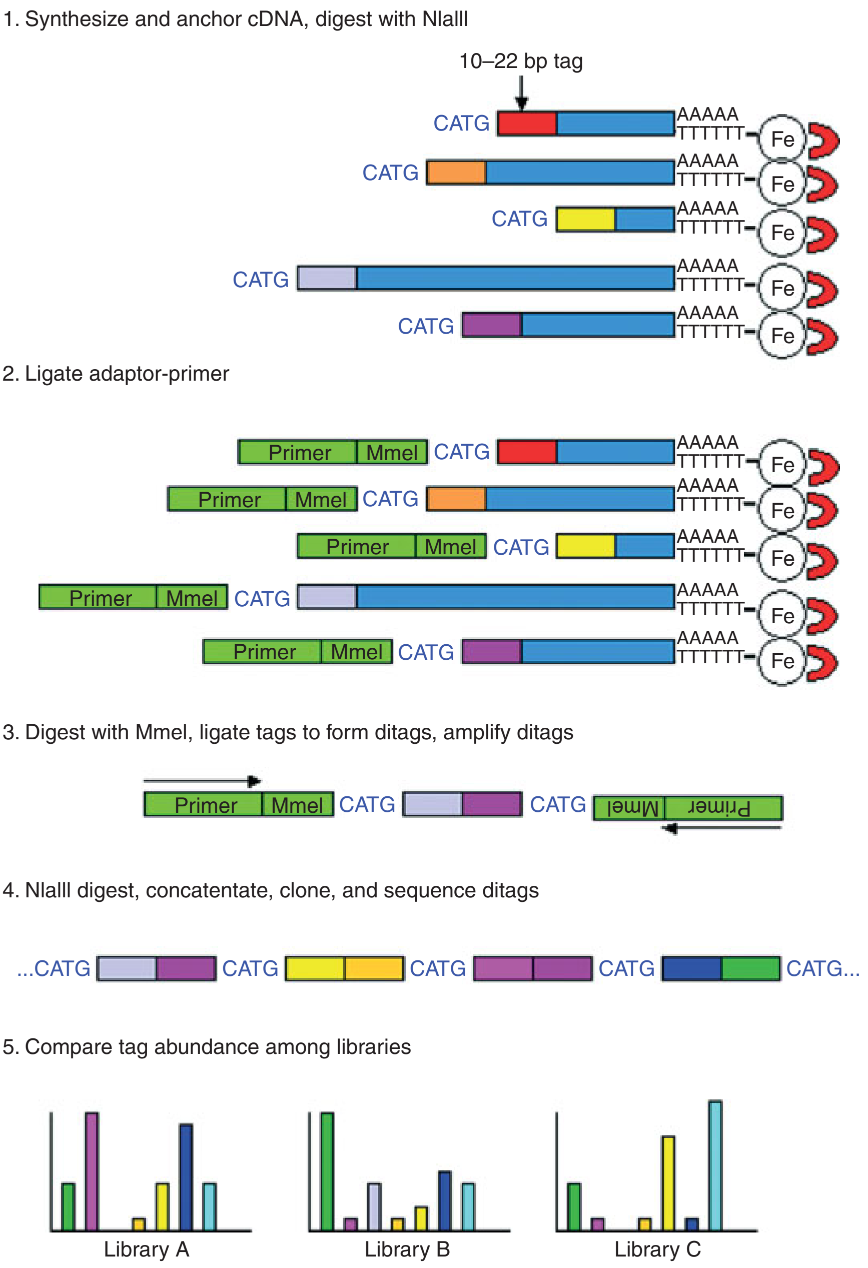

Figure 1 SAGE library construction and analysis

then isolated and sequenced (Figure 1, Step 4). Finally, SAGE tags are matched to genes using appropriate software, and tag abundance levels from the library of interest are compared to those from other libraries to identify differentially expressed genes (Figure 1, Step 5) where gene expression levels are determined simply by tag count. Duplicate ditags are discarded from the analysis, thus controlling for any tag-specific biases in PCR amplification.

3. Digital- versus hybridization-based expression profiling

Digital-based expression profiling technologies such as SAGE have a number of advantages over hybridization-based approaches such as microarray analysis (*see* Article 90, **Microarrays: an overview**, Volume 4). Digital-based approaches are nearly comprehensive – sampling all expressed genes, rather than being limited by one's choice of probes. Absolute levels of gene expression (i.e., individual tags as a percentage of total tags) are obtained – which making it straightforward to compare data sets obtained by different labs and large amounts of public digital expression data are already available from sites like the NCBI SAGE map project (**http://www.ncbi.nlm.nih.gov/SAGE**). It should be noted, however, that tag abundance measurements are more accurate for highly expressed transcripts than for those expressed at low levels. Only the widely used molecular approaches of cDNA library construction and DNA sequencing are used to generate the data, making it easy to initiate these studies. Very little experimental error is introduced in the construction of the libraries (Blackshaw *et al*., 2003), with PCR amplification biases being controlled by the elimination of duplicate ditags from analysis. The sensitivity of digital-based expression profiling is only limited by one's ability to sequence – one could, in principle, sequence enough tags to cover every mRNA in the sample of interest. Finally, since there is no hybridization background or variations in probe quality to consider, interpretation of digital gene expression data is quite straightforward and easily performed with a simple set of statistical tools (*see* Article 53, **Statistical methods for gene expression analysis**, Volume 7).

Hybridization-based systems have a number of advantages of their own, however, cost and speed being the main ones. Commercially available oligonucleotide arrays (*see* Article 92, **Using oligonucleotide arrays**, Volume 4) giving nearly complete coverage of the human genome can be hybridized in triplicate for ∼$3000, while constructing and sequencing 50 000 tags from a SAGE library can cost ∼$15 000. Furthermore, construction of SAGE libraries can require two weeks of work, and performing the required number of sequencing reactions can take months, while microarray hybridization can be completed in two days and many arrays can be run in parallel. The considerable variation in gene expression seen among biological samples (Blackshaw *et al*., 2003; Pritchard *et al*., 2001) is best controlled for by obtaining multiple replicates of expression profiles – a proposition that is difficult to accomplish with digital-based methods. Since all digital-based methods rely on sampling, the "real" tag count in a sample actually represents a Poisson distribution around the observed tag count in a library (Audic and Claverie, 1997), introducing a level of uncertainty that is unacceptable for certain studies. Though expression profiling of very small amounts of starting material (i.e., <1 µg total RNA) typically

requires amplification of the starting material and leads to skewed representation of certain transcripts, the comparative hybridization of amplified samples can control for this, making it the method of choice in such situations. Finally, variations in efficiency of cDNA-target hybridization among probes can result in expression of some rare genes being detected quite efficiently, whereas rare genes are only efficiently detected at high tag numbers by digital-based methods.

4. Hybridization or digital-based expression profiling – which to use?

The choice of a digital or hybridization-based approach to profiling gene expression depends to a large extent on one's experimental aims. If the primary aim of a study is gene discovery, or more generally, to analyze gene expression in a limited number of samples in great depth and at high resolution, digital-based methods such as SAGE are probably the method of choice. Digital-based methods are particularly well suited to generating publicly accessible databases of gene expression. Hybridization-based methods, on the other hand, are the method of choice when a large number of samples need to be screened or when very small amounts of starting material are used. More generally, hybridization-based approaches are probably the best choice for exploratory studies where a large initial investment of resources is not desired.

5. Comparison of SAGE with other methods of digital-based expression profiling

Since 20–40 SAGE tags are obtained with each sequencing reaction as opposed to 1 tag per reaction with conventional EST sequencing, SAGE is much more efficient at profiling gene expression than EST sequencing. Likewise, the great majority of public EST data is obtained from libraries that have been both normalized and subtracted, and thus do not accurately reflect mRNA levels in the sample in question. MPSS has many of the same advantages of SAGE and is, in principle, more rapid, although costs per sample are high at present and the technology is not widely available. Neither SAGE nor MPSS, however, gives extensive information about alternative splicing of mRNAs, and both approaches require a fully sequenced genome to be maximally useful. Conventional EST sequencing may be the method of choice in cases in which either of these factors is a concern.

6. Variations and choice of methodology in SAGE

A number of variations of SAGE have been developed in recent years, including the generation of 5′-anchored libraries using affinity to the 5′ cap structure or, in *Caenorhabditis elegans*, to the trans-spliced 5′ leader exon found in virtually all mRNAs (Hwang *et al*., 2004; Wei *et al*., 2004). The choice of SAGE tag

length varies with the complexity of the genome one is analyzing and the specific topic addressed. All things being equal, a shorter tag is preferable, since more tags can then be obtained in each sequencing reaction. Since each tag specifies 4^n possible combinations, where $n =$ tag length, a 10-bp tag can specify over 10^6 combinations – more than enough to unambiguously define the majority of transcripts in most organisms, provided cDNA sequences for the transcripts are available. However, to identify a unique match in genomic DNA and allow de novo transcript annotation, anywhere from 10^{10} to 10^{11} combinations must be specified, tags longer than 13 bp (13 unique bp + 4 bp from the NlaIII site = 4^{17} combinations) are required.

The number of tags sequenced will depend on the number of transcripts per cell in the sample tested, the sensitivity desired, and the cellular complexity of the sample examined. Abundant transcripts will be accurately profiled with relatively low tag counts, but rare mRNAs in abundant cell types or abundant mRNAs selectively expressed in rare cell types will require much higher tag counts to profile accurately.

Introductory Review

Core methodologies

Gerard Cagney
University College Dublin, Dublin, Ireland

There is no science without fancy, and no art without facts – Vladimir Nabokov

These are exciting times for proteomics. While technological progress at the frontiers of the science continues unabated, the basic ability to identify proteins in a mass spectrometer justifies much of the fuss. This section describes techniques that form the "bread and butter" of proteomics – techniques that are within the reach of many laboratories and are increasingly provided as "core facilities" within research institutes. Indeed, one of the major challenges is not merely technical but to communicate to the general research community exactly what proteomics can and cannot do. In this respect, Section 1, "Core Methodologies", goes some way to expounding the state of the art. Most of the methods described can be considered routine in a proteomics lab, yet they greatly extend the power of virtually any type of experiment involving proteins. The significance of protein and peptide ionization methods coupled to mass spectrometry (MS) was recognized by the award of the Nobel Prize for Chemistry in 2002 to John Fenn and Koichi Tanaka. But before the late 1990s, proteins were almost exclusively identified using antibody-based methods such as ELISA and western blot, or using Edman degradation for protein microsequencing.

Nowadays, researchers who can accurately and rapidly identify proteins have three very powerful advantages in pursuing their research goals. First, because protein identification can be achieved in a semiautomatic manner, the type of project that can be undertaken is greatly extended. Examples in this and subsequent sections range from the analysis of chemical modification of single proteins, to the characterization of protein complexes isolated by affinity precipitation, to examining the proteome dynamics of whole cells under conditions of health and disease. These studies are possible partly because the feedback cycle between experiment and result has been dramatically shortened with proteomics. It is therefore feasible to develop a new model in a reasonable amount of time, or to analyze more samples under more conditions in order to give greater statistical power. Second, researchers are not limited to identifying only those proteins for which tests (or antibodies) are available. Even where tests are available, they may not be uniformly sensitive or robust, making large-scale or parallel studies problematic or impossible. Meanwhile, although the goal of comprehensive genome-wide qualitative and quantitative analysis (already realized for mRNA)

is not yet a reality for proteins, recent studies in organisms such as yeast and the malaria parasite can clearly be described as "systemwide", with thousands of proteins being identified. A third advantage of proteomics is that all or most of the proteins in a sample can be identified, not just those specifically chosen for testing according to some criteria. This opens the door to chance discovery. Proteomics studies, in common with other so-called omics approaches, have sometimes been criticized for lacking central hypotheses, and these criticisms deserve to be taken on board. In the most satisfying work however, experiment design that directly addresses a hypothesis has been combined with the possibility of making new discoveries. In other words, hypothesis testing and discovery science need not be incompatible. If "finding out new things" is what makes for successful science, then we can expect many more successes from proteomics.

These successes are being driven by machines, mass spectrometers, whose origins, like much of molecular biology itself, can be traced to pioneering physicists like Joseph John Thompson and Francis William Aston at the beginning of the twentieth century. It would be a disservice to the many outstanding intellectual achievements to attempt to summarize the history of MS (mass spectrometry) here, but the key methods contributing to the analysis of peptides and proteins followed the development of soft desorption and ionization techniques, particularly, matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI). These methods allow large biomolecules such as peptides to enter a mass spectrometer. Getting biomolecules into the instrument as intact charged species was the major barrier to the development of the field. Both methods are discussed in these pages (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5), and it is interesting that both continue to be widely used with no single ionization method dominating to date. One may generalize and say that MALDI is more amenable to automation and high-throughput experimentation, while ESI has been adapted very successfully to separation methods such as liquid chromatography. Almost by definition, a scientist engaged in a proteomics experiment will be dealing with mixtures of proteins of some complexity, and in general, the complexity needs to be reduced before or during the ionization process. This is because of limits resulting from design of the various instruments, for instance, the duty cycle, the dynamic range, and signal saturation.

The complexity of proteomics samples is addressed through a mixture of sample preparation and component separation. Here, an overview of sample preparation is provided (*see* Article 2, **Sample preparation for proteomics**, Volume 5), including proteolytic digestion with trypsin, a very important method in most proteomics laboratories (*see* Article 16, **Improvement of sequence coverage in peptide mass fingerprinting**, Volume 5). Strategies to separate proteins may be applied to intact proteins or to their proteolytic digests. Often, separation by one feature of the chemistry of proteins or peptides is sufficient, but the complexity of many proteomic samples is such that at least one additional feature must be used. Two-dimensional gels (*see* Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5) separate proteins according to their isoelectric points and mass for instance, while the MUDPIT technique (Multidimensional Protein Identification Technology) separates peptides according to their charge and hydrophobicity (*see* Article 13, **Multidimensional liquid chromatography**

tandem mass spectrometry for biological discovery, Volume 5). Many variations are possible, constrained only by the need to keep the peptides solvated and ultimately to ionize them. Capture technologies that trap and separate proteins or peptides on the basis of the presence of moieties such as carbohydrate or phosphate groups have been described, and in principle, almost any type of chemistry that can separate proteins or peptides on the basis of their distinct chemistries can be exploited. However, unlike say oligonucleotides, proteins are chemically heterogeneous, and certain classes of proteins, while very important biologically, are difficult to adapt to normal sample preparation protocols. Here strategies that may be used to prepare membrane proteins for MS are described (*see* Article 15, **Handling membrane proteins**, Volume 5).

One trend that has been consistent across all types of proteomics technologies is miniaturization. This has been driven by factors such as the need to analyze thousands of proteins in parallel, limited amounts of sample, economics, and especially in the case of mass spectrometry, by the need for increased sensitivity. The development of micro- and nanoscale liquid chromatography was especially important, and both Nano-MALDI and Nano-ESI MS are described here (*see* Article 11, **Nano-MALDI and Nano-ESI MS**, Volume 5). A very useful description of making nanocolumns and tips is also included (*see* Article 19, **Making nanocolumns and tips**, Volume 5). This method can lead to very significant gains in the sensitivity of electrospray experiments with complex peptide mixtures. An important new technique for analysis at the cell and tissues level is laser-based microdissection (*see* Article 6, **Laser-based microdissection approaches and applications**, Volume 5), and this approach is likely to have important clinical research applications.

The range of different mass spectrometers can be overwhelming to the newcomer (and latecomer!). Both traditional and emerging aspects of the workhorse instruments are treated here: time-of-flight MS (*see* Article 7, **Time-of-flight mass spectrometry**, Volume 5), quadrupole MS (*see* Article 8, **Quadrupole mass analyzers: theoretical and practical considerations**, Volume 5), and quadrupole ion trap MS (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5). The most useful features of different architectures have been intelligently combined to create hybrid instruments (*see* Article 10, **Hybrid MS**, Volume 5). Similarly, the use of the extremely powerful class of Fourier transform ion cyclotron instrument is becoming more widespread (*see* Article 5, **FT-ICR**, Volume 5). An important aspect of these multistage MS techniques is the use of instrument software that automates the process. This is particularly the case for tandem mass spectrometry experiments where the ions chosen for fragmentation following a primary "scan" can be chosen using predetermined rules, eliminating the need for constant supervision of the experiment. As discussed (*see* Article 18, **Techniques for ion dissociation (fragmentation) and scanning in MS/MS**, Volume 5), tandem mass spectrometry is a major means of acquiring structural information about peptide molecules, particularly, the amino acid sequence. Normally associated with quadrupole or ion trap instruments, the somewhat related phenomenon of post-source decay means that this form of structural analysis can now be carried out by time-of-flight instruments, considerably extending its application.

However, it is often forgotten that the power of proteomics is not fully realized solely by a powerful instrument, or even by an optimal combination of separation method, ionization method, and instrument. Without the automated methods for interpreting mass spectra, these protein "signatures" would accumulate many times faster than the ability of skilled workers to determine what they represent. The development of algorithms and programs that assist the process of identifying proteins from their cognate mass spectra was therefore another key technological breakthrough, allowing the science of proteomics to evolve. Several workers in the early 1990s independently devised methods for using publicly available DNA sequence databases to reduce the task of interpreting protein and peptide mass spectra to a tractable problem. Although similar in principle, the approaches of peptide mass fingerprinting (*see* Article 3, **Tandem mass spectrometry database searching**, Volume 5) and tandem mass spectrum interpretation (*see* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5) require different programs. Tutorials describing both approaches included here will be very helpful (*see* Article 17, **Tutorial on tandem mass spectrometry database searching**, Volume 5).

The observation at the top of this text was made by Nabakov during an interview in 1966. Many of us are fortunate to arrive now onto a scene where approaches that required highly original thought and effort to develop are sufficiently embedded that we may cast our proteomic nets across the water in expectation of a plentiful catch. The work of these pioneering scientists should be applauded, as should the authors of the chapters following, many of whom are one and the same. To them we owe the ability of proteomics to combine fancy and facts.

Introductory Review

Advances of LC-MS and CZE-MS in proteome analysis

Hookeun Lee
Institute for Molecular Systems Biology, ETH Zürich, Switzerland

Ruedi Aebersold
Institute for Molecular Systems Biology, ETH Zürich, Switzerland
University of Zürich, Zürich, Switzerland

1. Introduction

Mass spectrometry (MS) is an essential core technology in proteomics, the comprehensive analysis of the proteins expressed in a cell or tissue (Aebersold and Goodlett, 2001). In the late 1980s, two new ionization methods were developed that have revolutionized the analysis of large biomolecules by MS.

Both methods, electrospray ionization (ESI, Fenn *et al*., 1989) and matrix-assisted laser desorption/ionization (MALDI, Karas and Hillenkamp, 1995), convert nonvolatile analytes like proteins and peptides to ions in gas phase without derivatization and minimal fragmentation. These ions are then selected to mass analysis. Because of the lack or minimal extent of analyte fragmentation during ionization, ESI and MALDI are also referred to as *soft* ionization methods (Aebersold, 2003). ESI generates ions by spraying a solution at atmospheric pressure through a small-diameter needle and by applying electric potential between the needle and the inlet of a mass spectrometer. Through evaporation and splitting, the size of the droplets is reduced. This desolvation process ultimately produces bare analyte ions in the gas phase, which are then transmitted to the mass spectrometer. Because of its solution-based nature, ESI is easily coupled on line with liquid phase separation techniques, particularly with high-performance liquid chromatography (HPLC) and capillary electrophoresis (CE). Furthermore, due to the propensity of ESI to produce multiple charged ions, simple quadrupole instruments and other types of mass analyzers with limited mass/charge (m/z) range could be used to detect ions with masses exceeding the nominal m/z range of the instrument (typically 0–4000 Da). For MALDI, analytes are cocrystallized with a UV-absorbing compound (matrix) on a sample probe. Pulses of UV laser light are used to vaporize small amounts of the matrix and analyte ions to produce protonated gas phase ions. The method is relatively resistant to contaminating species and, due to the propensity to generate predominantly singly charged ions, MALDI spectra are simple to explain (Aebersold and Goodlett, 2001).

Over the last decade increasingly sophisticated and powerful mass spectrometers for peptide analysis have been developed and interfaced with high-performance separation systems. Separations prior to MS analysis remove salts and other impurities and concentrate analytes in the narrow elution peaks, resulting in increased sensitivity. This review will focus on the recent advances of on-line high-performance separation techniques such as HPLC and capillary zone electrophoresis (CZE) for MS analysis in proteomics.

2. Reversed-phase microcapillary chromatography and ESI-MS

Nanospray ionization, a low flowrate ESI, gained wide popularity due to its high sensitivity. Wilm and Mann proposed that the desorption efficiency of analyte peptide ions from the electrosprayed droplet increases as the size of the droplets decreases. This is thought to be due to the larger surface area of the droplet in relation to its total volume (Wilm and Mann, 1996). As a result, a greater proportion of the available analyte molecules is ionized and transmitted to mass spectrometers. This enhanced sensitivity of the nanospray method reduced the amount of peptide required for MS analysis to a few femtomoles and below in the mid-1990s (Shevchenko *et al*., 1996). Efforts to miniaturize HPLC to utilize nanospray ionization in combination with on-line peptide separation lead to the development of packed microcolumns using fused silica capillaries with a 20–150-μm inner diameter (i.d.) and a flowrate of less than 1 μl min^{-1} (Ishihama, 2005; Moseley *et al*., 1991; Holland and Jorgenson, 1995; Emmett and Caprioli, 1994). Even though the sensitivity of MS analysis increases with decreasing column i.d., most microcapillary liquid chromatography (μLC) work is done with 75 or 100 μm i.d. capillary columns because these clog less frequently than capillary columns of ≤50 μm i.d. Using this microscale format, reversed-phase liquid chromatography has most often been combined with mass spectrometric analysis of a protein digest because the on-line separation also effectively removes contaminants such as salts and detergents that are detrimental to ESI performance. Figure 1 shows an integrated μLC/nanospray ionization device (Gatlin *et al*., 1998). The microcross works as a flow splitter providing nanoliter per minute scaled flow to the column and as a junction point of liquid and the metal wire supplying the electric potential required for nanospray ionization. One advantage of this type of device is the use of the capillary tip, tapered to ∼5 μm, to hold the C_{18}-derivatized particles in place rather than use of a sintered frit connected to a separate ESI emitter via a union. This design significantly reduces the dead volume and band broadening. This type of integrated device has gained popularity from work by Yates and coworkers (Gatlin *et al*., 1998), most notably as multidimensional protein identification technology (MudPIT) using a biphasic capillary column (Link *et al*., 1999).

The integrated device has been further developed by several groups (Yi *et al*., 2003; Meiring *et al*., 2002; Licklider *et al*., 2002). The main advantage is the introduction of a sample trapping and enriching precolumn to enable automated consecutive runs for high-throughput analysis. The precolumn allows decreased sample loading time, rapid sample desalting, and facilitates automation. Despite

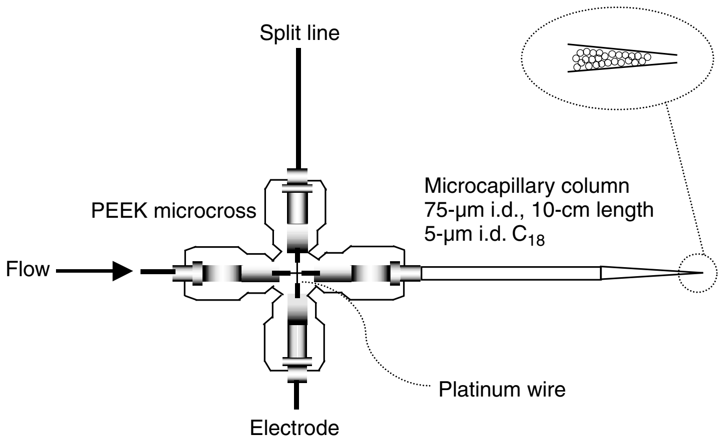

Figure 1 Schematic representation of μLC/ESI device

these advantages, the dead volume between the precolumn and the microcapillary analytical column can be a limiting factor. The consequent band broadening will decrease ESI sensitivity for those analytes present at low relative stoichiometry. To minimize the dead volume, a precolumn and a microcapillary column were integrated as one piece (Meiring *et al*., 2002; Licklider *et al*., 2002), or the two columns were placed in close proximity (Yi *et al*., 2003). The ruggedness and sensitivity of such devices was demonstrated by performing more than 60 consecutive μLC separations on complex peptide mixtures without degradation of chromatographic resolution and by detecting 1 amol of a standard peptide using a conventional ion-trap mass spectrometer (Yi *et al*., 2003).

Further increases of sensitivity into the zeptomole (10^{-21} moles) range was achieved by combining ultra high-pressure μLC separating at a pressure of 10 000 psi with Fourier transform ion-cyclotron resonance (FTICR) mass spectrometer (Shen *et al*., 2003; Belov *et al*., 2004).

Recently, Yin *et al*. (2005) have developed a novel integrated nano-LC/ESI microfluidic chip in which an enrichment column, a reversed-phase column (75-μm width × 50-μm depth × 40-mm length), and an ESI tip have been laser-ablated into a polyimide film. The compact format of the chip reduces the number of capillary tubing and fittings required and greatly simplify operation skills. It also facilitates troubleshooting for blockages and leakages in capillaries and connectors. Initial efforts using this chip coupled to ion-trap mass spectrometer have resulted in the identification of 47 protein clusters from albumin and IgG-depleted rat plasma sample by the chip separation alone, and 111 clusters by two-dimensional separation of strong cation exchange (SCX) chromatography and the chip (Fortier *et al*., 2005).

3. Capillary zone electrophoresis and ESI-MS

For CZE or simply CE, separations occur inside a capillary filled with a moderately conductive liquid. The degree of separation of analytes inside the capillary depends

on their relative electrophoretic mobilities under the applied electrical field. CE has been widely utilized for separations of proteins and peptides due to the high separation efficiency of the method that reaches $\sim 10^6$ theoretical plates, and high speed (Shen and Smith, 2002; Simpson and Smith, 2005). A critical disadvantage of CE, however, is the limited sample injection volume, typically below 20 nl ($\sim$1% of the total capillary column volume) (Shen *et al*., 2000), which limits the sample concentration and limits of detection. To overcome this limitation, various preconcentration methods have been implemented including sample stacking, transient isotachophoresis, and solid-phase extraction (Stroink *et al*., 2001). Among the various preconcentration methods, solid-phase extraction has been effectively coupled with CE for on-line interfacing with mass spectrometers. Figeys and coworkers used a microfluidic device integrating a C_{18}-based preconcentrator and CE for the analysis of protein digests (Figeys *et al*., 1999; Figeys *et al*., 1998).

ESI is the predominant method for interfacing CE to MS, while MALDI has also been used extensively. ESI-based interfaces divide into two categories: sheath-flow interfaces and sheathless interfaces (Schmitt-Kopplin and Frommberger, 2003; Moini, 2002). For the sheath-flow interface, a second tube of a larger diameter surrounds the separation capillary in a coaxial arrangement. The sheath liquid is driven through the outer tube by an external pump. The sheath-flow interfaces provide system stability and reduce the requirement for the background electrolyte to be compatible with ESI-MS. These advantages make those most widely used interface designs (Simpson and Smith, 2005). The main disadvantage of the sheath-flow configuration, however, is low detection sensitivity due to the dilution of the analyte by the sheath liquid (Moini, 2002). Sheathless interfaces offer higher sensitivity because there is no sheath liquid present to dilute the CE effluent. A variety of the sheathless interfaces have been reviewed by Issaq *et al*. (2004).

4. Conclusions

Major analytical challenges in proteomics are the enormous complexity of the proteome and the large variance in protein abundances. Thus, with advances in MS technology, the initial efforts of proteomics have focused on improving interfaces between the separation techniques and MS to increase detection sensitivity. Concurrently, another effort to combine other separation techniques, such as SCX, affinity chromatography, free-flow electrophoresis, capillary isoelectric focusing, and one-dimensional electrophoresis, with liquid chromatography - mass spectrometry (LC-MS) and CE-MS have been carried out to enhance the resolution and dynamic range of proteome-wide analysis (Han *et al*., 2001; Moritz *et al*., 2004; Chen *et al*., 2003; Aebersold and Goodlett, 2001). It can be expected that with these developments complete proteome analysis will become a reality.

Sample preparation for proteomics

Thierry Rabilloud
CEA-Laboratoire d'Immunochimie, Grenoble, France

1. Introduction

Sample preparation can be defined as the process that goes from the biological sample of interest to the final protein extract that can be handled by the desired proteomics method. This process has to achieve parallel goals:

- disruption of the initial structure of the biological material;
- prevention of any spurious degradation of the analyte (i.e., proteins);
- removal of compounds that can interfere with the further processing of the sample, for example, protein separation or chemical labelling or controlled digestion;
- keeping proteins soluble in conditions and media that are compatible with this downstream processing.

It can be easily seen that sample preparation strongly depends on the type of processing that will be used for the proteomics analysis *per se*. Two major subsets of sample preparation can be defined. In the first one, the protein–protein interactions must be kept as close as possible to the *in vivo* situation. This is of major importance when protein complexes are to be analyzed. In the second one, individual polypeptide chains are analyzed. In this case, separation of proteins into undegraded polypeptide chains must be achieved.

2. Native sample preparation

This means that the sample preparation must respect as much as possible the three-dimensional structure of the proteins, including the links that can exist between proteins. Whatever the subsequent separation method is, two main problems are encountered with these techniques. The first problem is to prevent degradation of the sample by hydrolases, especially proteases, which are very difficult to inhibit under the conditions that allow the three-dimensional structure of proteins to be kept intact. The second and most important problem is to keep the protein assemblies

as close as possible from their *in vivo* situation while keeping conditions that are compatible with downstream processing.

This poses in turn the problem of choosing extraction and purification conditions that look as similar as possible to those prevailing in a cell, but still being practicable. It must be recalled that a cytosol is a 10% by weight solution of proteins, that is, a milieu of very high viscosity and of rather unknown chemical parameters (dielectric constant, ionic strength, etc.). It is therefore obvious that weakly buffered water solutions do not represent a good model of the intracellular medium and that problems with protein assemblies in such media are likely to occur. However, increasing the ionic strength is probably not adequate, as this is known to extract many subunits from complexes. The work or Schägger and coworkers (Schägger and Von Jagow, 1991) can provide interesting tracks to follow. In this paper, it is shown that high concentrations of a dielectric compound (e.g., aminocaproic acid) dramatically enhances the extraction of protein complexes. Thus, dielectric compounds could show some of the beneficial effects of salts (salting in effects), without showing their dissociating effects. However, aminocaproic acid has a relatively low dipolar moment, and might not be the ideal dielectric compound. Chemicals with stronger dipolar moments such as sulfobetaines (Vuillard *et al*., 1995a) have been shown to increase protein solubility and may prove useful for protein complexes isolation. Their efficiency as salt mimics has been shown for the purification of halophilic proteins (Vuillard *et al*., 1995b). Thus, dielectric compounds with varying dipolar moments or hydrophobic parts may be worth testing to enhance the stability of protein complexes during their fractionation either by electrophoresis or chromatographic techniques.

Apart from these general parameters, sample preparation is also driven by the separation method used. When chromatographic separations are used, for example, by affinity chromatography (Rigaut *et al*., 1999), the conditions are relatively flexible for many parameters such as ionic strength or detergent choice. This is not the case when native electrophoresis is used (Schägger and Von Jagow, 1991). In this case, the ionic strength must be kept low and an ionic charge must be given to the extracted proteins. This is achieved either by the use of a specially designed detergent (Hisabori *et al*., 1991) or via a charged protein-binding molecule such as Coomassie Blue (Schägger and Von Jagow, 1991). Apart from its use for electrophoresis, this charge-shift process has the important benefit to increase protein solubility.

3. Denaturing sample preparation: general considerations

In this case, the constraint of keeping proteins intact is replaced by separating them as much as possible in the form of individual polypeptide chains. This means in turn breaking all bonds, keeping proteins together, and allowing binding to other compounds. Apart from disulfide bridges, most of these bonds are noncovalent interactions, for example, ionic bonds, hydrogen bonds, and hydrophobic interactions. These interactions can be broken by chaotropes, detergents (especially ionic ones), or a combination thereof, while disulfide bridges must be broken by special reagents. Here again, one of the major difficulties is

to prevent spurious degradation of the proteins by hydrolases. Under denaturing conditions, only very resistant hydrolases are active, that is, mainly proteases, but this can be a very important problem, especially when complete proteins are to be analyzed downstream. The problem is further enhanced by the fact that denatured, unfolded proteins are most sensitive to proteases, even if the latter are only partly active.

Last but not least, in many samples, protein denaturation induces removal of DNA-binding proteins from DNA, and thus massive swelling of DNA in the sample, correlating with increased viscosity and additional problems, depending on the downstream methods. Other nonproteinaceous compounds, such as salts or lipids, can also be deleterious for downstream methods and must be taken into account in the sample preparation protocols.

Biological samples are also generally very complex, and no single separation technique is able to resolve the sample into individual components. This means in turn that complex separation schemes, usually multidimensional (i.e., relying on different parameters), must be used. In most of these schemes, the interface process between the various separations is robust enough, so that the constraints applying to sample preparation are only those induced by the first stage of separation.

3.1. The case of disulfide bridges

Breaking of disulfide bridges is usually achieved by adding to the solubilization medium an excess of a thiol compound, most of the time dithiothreitol (DTT). However, DTT is still not a perfect reducing agent. Some proteins are not fully reduced by DTT. In addition, DTT must be used in an important excess over the protein disulfide bridges. This is a problem when thiol derivatization must be performed, as the derivatization agent will have to be present in a further excess over DTT. In these cases, phosphines are very often an effective answer. The reaction is stoichiometric, which allows us in turn to use very low concentrations of the reducing agent (a few millimolar). The most powerful compound is tributylphosphine, which was the first phosphine used for disulfide reduction in biochemistry (Ruegg and Rüdinger, 1977). However, the reagent is volatile, toxic, has a rather unpleasant odor, and needs an organic solvent to make it water-miscible. Dimethylsulfoxide (DMSO) or dimethylformamide (DMF) are suitable carrier solvents, which enable the reduction of proteins by 2-mM tributylphosphine (Kirley, 1989). These drawbacks have disappeared with the introduction of water-soluble phosphines, for example tris (carboxyethyl) phosphine, which seem however to be less potent reducers.

4. Denaturing sample preparation rationales for selected proteomics methods

The last part of this chapter will deal with sample preparation available according to the downstream proteomics approach. For space limitation reasons, only the

rationales can be detailed in this chapter, and detailed protocols can be found in the references cited herein.

4.1. *Sample preparation for proteomics based on zone electrophoresis*

In these proteomics methods, the separation process is split in two phases (e.g., Bell *et al*., 2001). The first phase is a protein separation by denaturing zone electrophoresis, that is, in the presence of denaturing detergents, most often sodium dodecyl sulfate (SDS). The second phase is carried out by chromatography on the peptides produced by digestion of the separated proteins. As mentioned above, this has no impact on the sample preparation itself, which just needs to be compatible with the initial zone electrophoresis.

This is by far the simplest case. Sample preparation is achieved by mixing the initial sample with a buffered, concentrated solution of an ionic detergent, usually containing a reducer to break disulfide bridges and sometimes an additional nonionic chaotrope such as urea. Ionic detergents are among the most powerful protein denaturing solubilizing agents. Their strong binding to proteins makes all proteins to bear an electric charge of the same type, whatever their initial charge may be. This induces in turn a strong electrostatic repulsion between protein molecules, and thus maximal solubility. The system of choice is based on SDS, as this detergent binds rather uniformly to proteins. However, SDS alone at room temperature, even at high concentrations, may not be powerful enough to denature all proteins. This is why heating of the sample in the presence of SDS is usually recommended. The additional denaturation brought by heat synergizes with SDS to produce maximal solubilization and denaturation, even of the most resistant proteases.

The use of SDS is not always without drawbacks. One of the most important is encountered when the sample is rich in DNA. A terrible viscosity results, which can hamper the electrophoresis process. Moreover, some protein classes (e.g., glycoproteins) bind SDS poorly and are thus poorly separated in the subsequent electrophoresis. In such cases, it is advisable to use cationic detergents. They are usually less potent than SDS, so that a urea-detergent mixture must be used for optimal solubilization (MacFarlane, 1989). Moreover, electrophoresis in the presence of cationic detergents must be carried out at a very acidic pH, which is not technically simple but still feasible (MacFarlane, 1989). This technique has however gained recent popularity as a double zone electrophoresis method able to separate even membrane proteins (Hartinger *et al*., 1996).

4.2. *Sample preparation for proteomics based on two-dimensional gel electrophoresis*

In this scheme, the proteins are first separated by isoelectric focusing (IEF) followed by SDS electrophoresis. The constraints made on sample preparation are thus those induced by the IEF step. One of these constraints is the impossibility to use ionic

detergents at high concentrations, as they would mask the protein charge and thus dramatically alter its isoelectric point (pI). Ionic detergents can however be used at low doses to enhance initial solubilization (Wilson *et al*., 1977), but their amount is limited by the capacity of the IEF system (in terms of ions tolerated) and by the efficiency of the detergent exchange process that takes place during the IEF step. Another major constraint induced by IEF is the requirement for low ionic strength, induced by the high electric fields required for pushing the proteins to their isoelectric points. This means in turn that only uncharged compounds can be used to solubilize proteins, that is, neutral chaotropes and detergents. The basic solubilization solutions for IEF thus contain high concentrations of a nonionic chaotrope, historically urea but now more and more a mixture of urea and thiourea (Rabilloud *et al*., 1997), together with a reducing agent and a nonionic detergent. While CHAPS and Triton X-100 are the most popular detergents, it has been recently shown that other detergents can enhance the solubility of proteins and give better performances (Chevallet *et al*., 1998; Luche *et al*., 2003). In this solubilization process, detergents play a multiple role. They bind to proteins and help keep them in solution, but they also break protein–lipid interactions and promote lipid solubilization. This is a problem in lipid-rich samples, in which the amount of detergent present in the sample preparation solution can be limiting. In this case, lipid removal should be included in the sample preparation process. However, lipid removal is based on protein precipitation in solvents in which lipids are soluble. The major problem is that many proteins cannot be solubilized from the precipitate under IEF-compatible conditions (e.g., Tastet *et al*., 2003).

Apart from lipids, IEF is also very sensitive to many other compounds, such as salts or nucleic acids, which must be removed from many samples. Salt removal is carried out either by dialysis or by precipitation of proteins (e.g., by trichloroacetic acid (TCA) or organic solvents). The classical drawback of these approaches is loss of proteins due to their sticking to the dialysis membrane in the former method and by being soluble in the precipitation medium or irreversibly precipitated in the latter method.

Nucleic acids are present at problematic concentrations in most cell extracts, not to speak of nuclear extracts. One removal method is digestion by nucleases, initially by a mixture of RNAses and DNAses (O'Farrell, 1975). As with most of enzyme-based removal methods, the main drawbacks are linked to the parallel action of proteases (Castellanos-Serra and Paz-Lago, 2002), thereby degrading the proteins, and to the addition of extraneous proteins (the nucleases). A more versatile strategy is to use a high pH during extraction, so that most proteins are anions and are repelled from the anionic nucleic acids. To avoid overswelling of the nucleic acids, which decreases the subsequent removal by ultracentrifugation, this increase of pH can be mediated by the addition of a basic polyamine (e.g., spermine, Rabilloud *et al*., 1994), which will precipitate the nucleic acids. However, the most basic proteins are still cations at the pH 10 obtained in the spermine extraction method, and thus stick to nucleic acids. Extraction of these basic proteins can be obtained either with competing cations such as protamine (Sanders *et al*., 1980) or lecithins at acid pH (Willard *et al*., 1979). These methods are efficient but introduce high amounts of charged compounds, so that only low sample amounts can be loaded.

Another method is based on TCA precipitation (Damerval *et al*., 1986), which denatures nucleic acids and gives them a positive charge, thereby repelling the proteins. While this method is able to extract basic proteins such as ribosomal proteins (Görg *et al*., 1998), some proteins are lost at the resolubilization step after precipitation.

Another major problem encountered in sample preparation for two-dimensional electrophoresis resides in proteolysis. While ionic detergents are known to efficiently inactivate proteases, urea and nonionic detergents are unable to do so, as recently shown for example on yeast extracts (Harder *et al*., 1999). Thorough protease inactivation is clearly not an easy task. Most efficient methods are based either on TCA precipitation (with the risk of protein losses) or on the use of ionic detergents, which is always limited. It has been recently described, however, that thiourea helps in preventing spurious proteolysis (Castellanos-Serra and Paz-Lago, 2002).

4.3. Sample preparation for peptide separation-based approaches

In these methods, the sample preparation process is designed to offer optimal digestion of the proteins into peptides. This means that proteins must be extracted from the sample and denatured to maximize exposure of the protease cleavage sites. This also means that the protease used for peptide production must be active in the separation method. In this case, the robustness of many proteases is a clear advantage. Classical extraction media usually contain either multimolar concentrations of chaotropes or detergents. In the latter case, the sample is usually solubilized and denatured in high concentrations of ionic detergents, and simple dilution is used to bring the detergent concentration down to a point compatible with other steps such as chemical labeling or proteolysis.

The choice between chaotropes and detergent is driven mainly by the constraints imposed by the peptide separation method. In the wide-scope approach based on on-line two-dimensional chromatography of complex peptide mixtures (Washburn *et al*., 2001), both the ion exchange and reverse-phase steps are very sensitive to detergents. It must be mentioned that these on-line two-dimensional chromatographic methods are one of the rare cases in which the interface between the two separation methods does not bring extra robustness, so that the sample preparation must be compatible with both chromatographic methods. The modification approach (Gevaert *et al*., 2003), which uses extensive reverse-phase chromatography, is also very sensitive to detergent interference. This rules out the use of detergent and favors the use of chaotropes, generally nonionic ones because of the ion exchange step. Urea is used for these methods, with possible artifacts induced by urea-driven carbamylation of the sample during the lengthy digestion process. Inclusion of thiourea and lowering of the urea concentration could decrease the incidence of carbamylation in these methods. In methods in which a detergent-resistant method is used, for example, avidin selection of biotinylated peptides (Gygi *et al*., 1999), extraction by SDS is clearly the method of choice, as the above-mentioned drawbacks are absent.

5. Concluding remarks

It should be obvious from the above that the sample preparation process is dependent on many parameters that are sample-dependent, such as protein concentration, protein–lipid and protein–nucleic acid ratios, and so on. This explains why sample preparation, although critical for the quality of the final proteomics results, is so ill mastered and is likely to stay so.

Specialist Review

Tandem mass spectrometry database searching

Jimmy K. Eng, Daniel B. Martin and Ruedi Aebersold
Institute for Systems Biology, Seattle, WA, USA

1. Introduction

Mass spectrometry (MS) has become a principal technology in proteomics analysis largely due to improvements in sequence database availability and development of software tools to interpret mass spectra. Software tools of the modern proteomic era were first published around 1990 (Johnson and Biemann, 1989; Bartels, 1990; Yates *et al*., 1991). These programs facilitate the de novo sequencing process that became possible after collision-induced dissociation (CID) was shown to induce peptide fragmentation primarily along the amide backbone. In 1993, the era of sequence database searching began using protein fingerprinting or peptide mass mapping, with the development of software to query sequence databases with protein digestion products. This method remains in use today as it is fast and relatively accurate, but typically requires purified proteins as input substrate such as those excised from a gel spot or band. Despite these advances, the rapid adoption of MS as a proteomics platform is directly correlated with the automation of computational tools for the analysis of spectra from peptides analyzed by tandem mass spectrometry. As a peptide-centric identification strategy, MS/MS database searching or peptide fingerprinting allows for the analysis of mixtures of unseparated proteins such as those from protein complexes or whole-cell lysates. This review will touch on computational methods associated with peptide identification using MS/MS sequence database searching.

One of the earliest attempts to combine MS/MS analysis with database search strategies was published by Mann and Wilm (1994). Their method queried sequence databases with "peptide sequence tags", which are short amino acid sequences obtained by partial de novo sequence interpretation of tandem mass spectra combined with the corresponding mass constraints of the start and end mass of the sequence interpretation within the tandem mass spectrum. Sequence tag searches can be performed quickly because string matches can be coded efficiently and the database search space is typically limited to the analysis of peptides generated from an in silico enzymatic digestion of the database entries. Additionally, by relaxing search constraints such as the prescribed peptide mass, the sequence tag approach can identify interesting posttranslational modifications and homologous sequences

(Shevchenko *et al*., 1997). The major drawback to the sequence tag approach is the tag generation process as it has historically been performed manually. This is a rate-limiting step particularly when one considers the extraordinary rate at which modern mass spectrometers can acquire tandem mass spectra. Sequence tags can be generated in an automated fashion; however, automated tag-generation success rates are typically limited to good-quality spectra in the tag interpretation region and, in the case of ions generated by electrospray ionization, to the tags that are generated from a specific precursor ion charge state (Tabb *et al*., 2003).

The year 1994 also saw the first published method of querying uninterpreted tandem mass spectra of peptides against sequence databases (Eng *et al*., 1994). The embodiment of the described program, SEQUEST, uses a two-stage score function. The first stage generates a preliminary score for all peptides in a sequence database on the basis of summed ion intensities of a processed spectrum, with preliminary score adjustment factors for ion continuity, immonium ion contributions, and the percentage of fragment ions matched. The second stage of the score function, applied to the 500 best preliminary scoring peptides, generates a cross-correlation score between each theoretical and acquired tandem mass spectra. The cross-correlation score used in SEQUEST is effectively the correlation coefficient or vector dot product computed between the two spectra with a correction factor. Putative peptide identifications are ranked and reported on the basis of the cross-correlation score. Information from the preliminary score, such as the preliminary score rank and percentage of matched fragment ions, are also useful indicators for assessing positive identifications and are reported as well. Subsequent publications describe applications of the algorithm to identify posttranslational modifications (Yates *et al*., 1995a), query of nucleic acid sequence databases (Yates *et al*., 1995b), application to spectra generated by different instruments (Griffin *et al*., 1995; Yates *et al*., 1996), implementation to run on parallel computer clusters (Sadygov *et al*., 2002), and a modification to normalize the cross-correlation score for length dependence (MacCoss, 2002). SEQUEST is among the most widely used search algorithms.

In 1999, Perkins *et al*. published a search tool named *Mascot* that queries uninterpreted tandem mass spectra among one of its search options (Perkins *et al*., 1999). The Mascot score function is based on the MOWSE scoring algorithm (Pappin *et al*., 1993) previously used in peptide mass fingerprinting but modified to be probability-based. Although the direct details of the implementation of the score function are unpublished, it is likely that statistics on fragment ion frequencies, the direct extension of the MOWSE peptide mass statistics, are the major component of the score function. It has been noted that for each candidate peptide, Mascot iteratively searches a spectrum's peak intensities to find the set of most intense peaks that yields the maximum score. Using this method, the optimal number of peaks in a spectrum are independently determined and scored for each peptide in a database. The database search scores are interpreted as p-values and significant peptide identifications are based on the p-value scores. Owing to its independent development, fast searches, and probability-based score function, Mascot has garnered popularity as it facilitates the analysis of data acquired from most of the major instrument manufacturers.

Bafna and Edwards (2001) implement a probabilistic model for MS/MS database searching in a program named SCOPE. The score function in SCOPE incorporates fragment ion probabilities, spectral noise, and instrument measurement error. The authors employ a two-stage stochastic model for the observed MS/MS spectrum, given a peptide. The first step generates fragment ions from peptides, given a probability distribution estimated from training data. For this step, sufficient training data were not available to learn the values empirically so the authors defined the probabilities on the basis of consultation with "experienced mass spectrometry operators". The second step generates a spectrum using these fragment ions according to a distribution based on known instrument measurement error. Peptides are scored by the probability they would give rise to the observed spectrum, as opposed to all alternative spectra. Dynamic programming is used to efficiently sum up contributions from each possible pattern of peptide ion fragmentation. Since the scores for each peptide with respect to an observed spectrum are computed independently of all other peptides under consideration, it is not impossible for several peptides to receive equally high scores. The authors thus compute an additional p-value aimed at estimating the likelihood that each peptide score arose by chance. Although only 28 MALDI-TOF-TOF test spectra are used to evaluate the scoring scheme, the prototype implementation demonstrates the effectiveness of the model as 26 of the 28 spectra are identified correctly with scores significantly separated from the incorrect peptides. Additionally, the two incorrect identifications exhibited scores not well separated from the other top-scoring peptides in each particular search. This indicates that the significance test can differentiate correct from incorrect identifications, at least in this small set.

Havilio *et al*. (2003) describe a computational method using a statistical scoring approach based on the probability of detecting fragment ions in the experimental spectrum that incorporates a measurement of ion intensity. A set of score functions is developed using parameters incorporating both experimental observations and theoretical knowledge of peptide fragmentation. Examples of parameters used in the score functions include terms for random or noise peaks, the relative intensity of a given fragment ion peak, and the relative frequency of unmatched fragment ion peaks. The authors generate their own test set of highly probable peptides to evaluate fragment ion statistics. To do so, a large dataset collected from 46 LC-MS/MS runs of an ion trap mass spectrometer is analyzed. The score function used in the de novo sequencing program described in Dancik *et al*. (1999) is implemented and the criteria for highly probable peptides, those that pass a p-value of .01 cutoff, exhibit over 50% matched fragment ions, and are greater than 10 amino acid residues in length, are used to generate statistics for Havilio's model. These include, for each fragment type, the probability of detecting an ion of a given intensity across a range of fragment mass to peptide mass ratios, the probability of failing to detect a fragment ion across the fragment mass to peptide mass range, and the probability of a random ion of a given mass to have a particular intensity. The authors implement two score functions, intensity-based and non-intensity-based, using these statistics, with specific details described in the manuscript. Presumably tested on the same data used to generate the ion statistics, the manuscript shows that the intensity-based statistical scorer exhibits significant improvements over

the non-intensity-based scorer, the initial score function of Dancik *et al*., and an implementation of the cross-correlation score function as presented in Eng *et al*.

An approach to identify peptides through sequence database searching using Bayesian statistics is implemented by ProbID (Zhang *et al*., 2002). This Bayesian approach attempts to quantify the likelihood that the query spectrum is generated from a given candidate peptide sequence in the database. Background information used in computing the probability includes the protease used to digest the input sample (which is used in the score function and not as a peptide filter in the database search itself), immonium ion presence, matched and unmatched ions, and consecutive or complementary matched fragment ions referred to as a pattern match. Relatively simple models are used to compute contributions for each of the background information types. For example, a normal distribution around each theoretical ion is used to weigh matched ions on the basis of their distance from the theoretical peak. The standard deviation of the normal distribution is defined by the user-specified mass accuracy of the input data. Similarly, the total number of unmatched ions is counted and used as an exponent for a term involving just the mass difference between the highest and lowest peak in the experimental spectrum. The authors compare ProbID against SEQUEST on two reference datasets and show that both software tools similarly identify a majority of the peptides correctly. However, a still significant ∼10% of the identifications are detected by only one of the search engines. In summary, this manuscript shows that a relatively simple Bayesian probabilistic score function can perform as well as an industry standard tool including identifying spectra not identified by SEQUEST.

Hernandez *et al*. introduce a new method for protein identification using MS/MS data, named *Popitam*, that uses a nondeterministic heuristic approach to confront the combinatorial problems associated with analyzing modified peptides (Hernandez *et al*., 2003). This problem causes extraordinary increase in search times as sequences that have multiple potential modification sites require an independent search for each combination of modifications. Popitam's algorithm selects a given number of peaks in a spectrum, transforms the peaks into a spectrum graph, and compares them against a sequence database to generate a list of scored candidate peptides. (A spectrum graph is a mathematical representation in which peaks in an MS/MS spectrum are represented as nodes in the graph. Linking the nodes with edges that differ by amino acid residue masses generates a peptide sequence.) The initial implementation of Popitam, referred to as the "Full Path algorithm", works by looking for complete paths through the MS/MS spectrum graph where the sequence database is used to direct the search for matched sequences. If the spectrum graph contains gaps of two or more fragmentation positions, the initial algorithm struggles to identify peptides of these spectra because a full path through the graph is required. In Popitam's "Tag algorithm", short tags are generated where the sequence database is used to direct and emphasize relevant sections in the graph from which tags can be generated. As the tag discovery process can be combinatorially complex, a heuristic search using Ant Colony Optimization (ACO) is performed. In this implementation, ACO (inspired by the pheromone trail laying and following behavior of real ants) is a method of exploring different solutions to find good scoring paths in the spectrum graphs. The resulting ant score is a combination of terms such as the coverage measure between database

peptide sequence and the generated sequence based on parsing the spectrum graph, and a regression score representing the quality of the correlation between the experimental masses included in the path through the spectrum graph and the corresponding theoretical masses computed from the database peptide sequence. With the tag algorithm, combining unconnected relevant sections of the graph in order to maximally cover the theoretical peptides suggests that Popitam will be able to identify mutated or modified peptides without any prior knowledge of the modification.

A fragment ion frequency–based model by Sadygov *et al*. uses a hypergeometric distribution and is named PEP_PROBE (Sadygov and Yates, 2003). The theory involves formulating a model based on the frequency of fragment ion matches. The hypergeometric distribution is related to the binomial distribution but handles cases of sampling without replacement, in this case, the sampling of matched fragment ions. Four variables are used to calculate the hypergeometric probability. The first term is the total number of theoretical fragment ions in a sequence database for peptides of a given mass. The second term is the number of these theoretical fragment ions that match a peak in the input spectrum. The third term is the number of possible fragment ions for the peptide sequence being scored. The last term is the number of matched fragment ions for the peptide sequence being scored. To assess the significance of peptide matches, the authors implement a p-value that is calculated from the cumulative hypergeometric distribution. An implementation of the hypergeometric algorithm considering only b- and y-ions is tested against a set of approximately 59 000 ion-trap MS/MS spectra that contains 5000 true identifications. An analysis against this characterized dataset shows that false-positive error rate of 50% to less than 5% can be achieved depending on how high the score threshold cutoff is set. However, there is no mention of the corresponding sensitivity rates for each displayed error rate.

The MS/MS database search methods presented above are only a selection of the published tools in this growing field of computational proteomics. MS-Tag (Clauser *et al*., 1999), which implements the MOWSE score function, mutant tolerant identifications with PENDATA (Pevzner *et al*., 2001), vector dot product analysis with Sonar (Field *et al*., 2002), and signal detection theory and extended matches in OLAV (Colinge *et al*., 2003) are other noteworthy database search tools not covered in detail here. However, research and development in MS/MS database searching has gone beyond simply finding the optimal score functions used in MS/MS database searching. A new class of software tools have recently been developed that do not currently perform MS/MS database searches but rather assist in distinguishing between correct and incorrect database search assignments, as produced by the search tools described above. Three models have been described: one statistically based model, one model centered on machine learning using full datasets, and one intensity-based machine-learning model. A fourth introduces the concept of ion mobility and how peptide composition and charge affect MS/MS fragmentation and thus database search analysis.

Moore *et al*. have developed an analysis tool called *Qscore* to evaluate the quality of SEQUEST search results at the protein level that the authors suggest may decrease false-positive assignments and manual curation time (Moore *et al*., 2002). This algorithm is pseudo-probability based as it incorporates a quality

score of an individual peptide match into a calculation of the probability that a protein identification has occurred by chance. The probabilistic portion of the calculation is based on the number of peptides identified from a particular protein, the number of tryptic peptides from the particular protein in the database, and the total number of identified peptides. The quality score portion of the score is calculated in a fashion similar to SEQUEST where the spectrum is divided into a number of small m/z bins. The total ion current of each bin in a normalized measured spectrum is multiplied by the total ion current in the same range in a normalized predicted spectrum and all products are summed to a single value. A perfect match in this algorithm gives a quality score of 1. The quality score is converted to a probability by taking the inverse of 1 minus the quality score. The composite Qscore incorporates this quality score into the probability calculation. Testing by the authors produced good correlation with hand curation with reduced false-positive results.

Keller *et al*. introduced a method based on the use of the expectation maximization (EM) algorithm to derive a mixture model of correct and incorrect peptide identifications from the data (Keller *et al*., 2002). The software tool, PeptideProphet, learns to distinguish between correct and incorrect peptide identifications based on observed information, primarily database search scores and other peptide properties, from each peptide in a dataset. Peptide properties that are used to discriminate between correct and incorrect identifications include the difference between the observed versus calculated peptide masses, the number of missed enzymatic cleavage sites, and the number of peptide termini consistent with the expected enzymatic cleavage. A peptide discriminant score optimally combines the individual search scores, such as those produced by SEQUEST, into a single discriminant score. The coefficients of the discriminant function are developed for each type of MS/MS database search program and can be optimized for each type of mass spectrometer. On the basis of the distribution of scores mapped through the discriminant function, PeptideProphet applies EM to find mixture model distributions, Gaussian for the positive population and gamma for the negative population, that best fit the observed data. Other parameters of the data, such as the distribution of correct enzymatic termini exhibited by the positive and negative populations, are also automatically learned. Using the learned distributions of the positive and negative populations, PeptideProphet assigns computed probabilities (as opposed to p-values) that, in an implementation using ion trap data with the SEQUEST database search program, are shown to accurately reflect the confidence of peptide identifications being correct. Such accurate computed probabilities furthermore enable the prediction of false-positive error rates. The algorithm learns the correct and incorrect peptide assignments from the information in each individual dataset, rather than relying on a single set of universal parameters, which makes it tolerant of variations in factors such as data quality and protease digestion efficiency. Additionally, because PeptideProphet can be extended to analyze data generated from various mass spectrometers and run through different search engines, it can serve to standardize publication criteria and facilitate comparisons of large-scale datasets, particularly if data of a constant error rate are reported. It should be noted that the authors extend this peptide analysis to identifying proteins with the tool ProteinProphet (Nesvizhskii *et al*., 2003).

Elias *et al*. describe an intensity-based model developed using a machine-learning algorithm on 27 000 high-quality 2+ peptide-spectrum matches (Elias *et al*., 2004). This strategy uses a decision tree to model the probability of seeing a fragment ion based on 63 peptide fragment attributes. The decision tree was also applied to a set of mismatched peptides (the second best peptide from the high-quality matches). The authors calculate the likelihood of observing each fragment ion from a potential peptide match using both trees and calculate an odds ratio for that fragment ion. The individual odds ratios for each peptide are summed to generate a cumulative odds ratio (LOD score) for that peptide match. The authors tested their LOD score against other commonly used single scoring tools, such as SEQUEST's XCorr and dCn, and were able to demonstrate better sensitivity (proportion of correct identifications noted as correct) and specificity (proportion of incorrect identifications noted as being incorrect) than any of the commonly used strategies. In the authors' analysis, the LOD score performed approximately as well as the discriminant score used in PeptideProphet and when combined with the Xcorr and dCn had a slight advantage in specificity for a given sensitivity; comparisons against the full PeptideProphet analysis were not performed. The authors tested a publicly available dataset previously evaluated using a standardized scoring system and report finding 24% more correct identifications at the same false-positive rate using a LOD-based analysis.

Kapp *et al*. mined a database of 5500 tandem mass spectra of unique peptides obtained by tryptic digestion in order to determine which factors affect tandem MS fragmentation under low-energy CID conditions (Kapp *et al*., 2003). A residue's preference for cleavage (N- or C-terminus) was determined on the basis of two independent methods. First, a cleavage intensity ratio (CIR) value is calculated to quantify the extent of fragmentation occurring both N- and C-terminal to each amino acid residue within a peptide. The CIR is calculated by dividing the summed intensity for each amide bond cleavage by the average intensity of all cleavage sites within a peptide. CIR values greater than 1 indicate enhanced cleavage and below 1 indicate reduced cleavage. Second, a linear model that takes into account positional factors as well as peptide length was used to determine whether certain residues showed a propensity to cleave N- and/or C-terminal. Linear regression was performed to estimate effects of variables, such as the relative position of the cleavage along the peptide backbone and the specific effect of the adjacent amino acid on either side of the cleavage site, in order to select and retain only those variables that have a real effect on the fragmentation process. On the basis of using both CIR values and the linear model, the authors have classified peptides as nonmobile if the number of available protons is less than or equal to the number of arginine residues. For the remaining peptides, if the number of available protons was greater than the number of arginine residues but less than or equal to the total number of basic residues (arginine, lysine, and histidine), these were classified as partially mobile, otherwise, they were classified as mobile (more protons than basic residues). This has been termed the relative proton mobility scale. Analysis of SEQUEST and Mascot against the 5500 unique manually validated peptide MS/MS spectra shows that the search score varies considerably depending on the charge state and proton mobility classification. In relation to MS/MS database search, two conclusions can be drawn from this analysis. The first is that search

algorithm cutoff filters or score thresholds perform poorly for certain classes of spectra (e.g., nonmobile peptide), so score cutoffs should be reevaluated by taking into account the relative proton mobility scale described. Second, score functions can be improved by taking into account fragment ion abundances that are based on sequence, charge state, and proton mobility classification.

2. Conclusion

Database search software has made extraordinary strides in the last 10 years. Numerous programs now exist to allow rapid assignment of peptides of uninterpreted spectra. Many such programs are quite good and easily implemented for both large and small laboratories. Comparisons show that a number of the best search programs are fairly similar in their performance, each finding roughly similar numbers of peptides and assigning identifications to a few spectra "invisible" to other algorithms. Novel algorithms show promise of higher sensitivity at a given error rate compared to existing tools but need to be validated for real-world applicability. The future will almost certainly bring advances in allowing assignment to modified peptides as well as a refinement of search criteria as large datasets become available for testing. Further, the era of manual curation is coming to a conclusion, with the development of software that can assign a quality or probability score to a peptide assignment on the basis of a variety of spectral features or search scores. These developments will likely culminate with tools that allow rapid optimization for a set of experimental conditions such as MS platform and enzymatic treatment, ultimately streamlining sampling processing in both high- and low-throughput environments.

Specialist Review

Interpreting tandem mass spectra of peptides

Richard S. Johnson
Amgen Corporation, Seattle, WA, USA

1. Introduction

Given the success of database search programs at identifying proteins (Clauser *et al*., 1999; Eng *et al*., 1994; Fenyo *et al*., 1998; Mann and Wilm, 1994; Perkins *et al*., 1999), one could reasonably question the importance of knowing how to manually interpret tandem mass spectra (MS/MS) of peptides. This is especially true when working in a high-throughput environment where the data load precludes any sort of manual evaluation. Nevertheless, it can be intuitively grasped that occasionally looking at data might have some benefit. In addition to developing a sense of mass spectral aesthetics, and therefore an eye for data quality, knowing how to sequence peptides is essential when working with organisms for which no extensive sequence database is available. However, for organisms with sequenced genomes, this skill may still be important for validating database matches. Such validation is essential when a database search reveals only one or two peptides matching to a particular protein, which is frequently the case for experiments involving amino acid–specific fractionation (e.g., ICAT; Gygi *et al*., 1999). In addition, anyone who has ever performed a database search using hundreds of spectra obtained from an LC/MS/MS experiment has found that well over half of the spectra do not match with anything. The more curious among us might wonder what gives rise to all the unmatched data, and whether there is anything to be learned from it. For example, the author once sequenced a number of carbamylated peptides (carbamylation was not considered in the database search). This information was useful for subsequent experiments. The scope of the following tutorial is limited to determining sequences from MS/MS spectra resulting from low energy collision induced dissociation of positively charged (protonated) peptides in which the majority of the fragment ions are singly charged.

2. Peptide fragmentation

For low-energy CID MS/MS spectra, the only sequence-defining fragmentations are the so-called *b*-type and *y*-type ions (Figure 1a). These ion types arise via

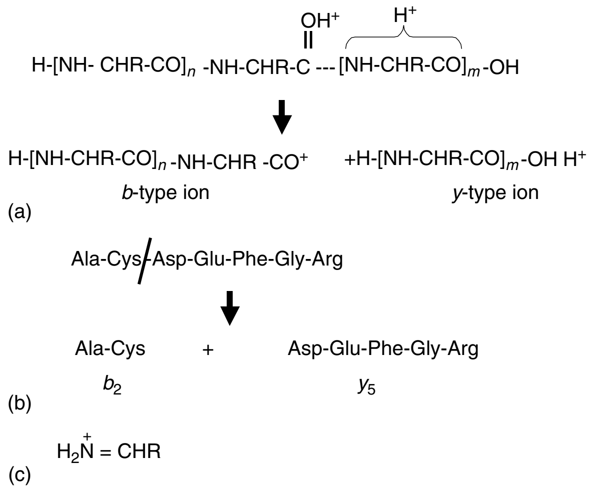

Figure 1 Peptide fragment ions. (a) A doubly protonated peptide has one proton sequestered within the C-terminal portion of the molecule and the other is protonating the carbonyl oxygen. This latter protonation weakens the amide linkage (dotted line) to the point that the peptide ion fragments into a C-terminal y-type ion and an N-terminal b-type ion. (b) This example indicates that b- and y-type ions are numbered according to the number of residues each ion contains. (c) Structure of immonium ions

a protonation of the peptide backbone, which subsequently weakens the amide linkage to the point that cleavage between the nitrogen and carbonyl carbon is favored. The y-type and b-type ions can both lose a molecule of water (18 Da) or ammonia (17 Da) in secondary fragmentations; in addition, the b-type ions can lose a molecule of carbon monoxide (28 Da) to give rise to a-type ions. These sequence-specific ions are labeled according to the number of residues they contain (e.g., Figure 1b). To calculate the mass of a specific b-type ion for a known peptide sequence, one sums the relevant amino acid residue masses (Table 1), and then adds the mass of the N-terminal proton. For y-type ions, the residue masses are summed, and the mass of the C-terminal −OH group is added, plus two additional protons (one for the N-terminus and one to provide the charge).

For the sake of simplicity, Figure 1a depicts b-type ions as acylium cations. However, it is currently thought that a more likely reaction mechanism involves nucleophilic attack of the protonated carbonyl carbon by the adjacent carbonyl oxygen located N-terminal to the cleavage site (Arnott *et al*., 1994; Schlosser and Lehmann, 2000). This would result in a five-member oxazolone ring structure on the C-terminal end of b-type ions. Such a fragmentation mechanism is appealing in that it accounts for certain well-known observations. First, one does not observe b_1 ions (b-type ions comprised only of the N-terminal amino acid in the peptide) for peptides with free N-termini, since there is no carbonyl group to induce cleavage. In contrast, if a carbonyl is added to the N-terminal amino group, either by acylation or carbamylation, such modified peptides can fragment to produce b_1 ions. Second, fragmentation on the C-terminal side of proline residues is much reduced, since the side chain ring structure constrains the attack of the carbonyl.

Table 1 Masses for monoisotopic amino acid residues (defined as −NH-CHR-CO-) calculated using all light isotopes. To calculate the mass of a *y*-type ion, sum the appropriate residue masses and add 19.0184 (three hydrogen plus one oxygen); to calculate the mass of a *b*-type ion, sum the appropriate residue masses and add 1.0078 (hydrogen atom)

Amino acid	Single-letter code	Mass
Glycine	G	57.0215
Alanine	A	71.0371
Serine	S	87.0320
Proline	P	97.0528
Valine	V	99.0684
Threonine	T	101.0477
Cysteine	C	103.0092
Isoleucine	I	113.0841
Leucine	L	113.0841
Asparagine	N	114.0429
Aspartic acid	D	115.0270
Glutamine	Q	128.0586
Lysine	K	128.0950
Glutamic acid	E	129.0426
Methionine	M	131.0405
Histidine	H	137.0589
Oxidized methionine		147.0354
Phenylalanine	F	147.0684
Arginine	R	156.1011
Carbamidomethylcysteine		160.0307
Tyrosine	Y	163.0633
Tryptophan	W	186.0793

A few ion types are observed that are not sequence specific. When a *b*-/*y*-type fragmentation (Figure 1a) occurs twice in the same molecule, one generates the so-called internal fragment ions. These possess neither the C- nor N-termini, and have a structure analogous to a *b*-type ion that is missing a piece of the N-terminus. These are particularly prominent when proline is on the N-terminal side of the internal fragment, and they rarely contain more than two to four amino acids. Immonium ions are composed of protonated single amino acid residues that have eliminated a carbon monoxide molecule (Figure 1c).

Shown in Figure 1a is the presence of a fragmentation-promoting proton located on the carbonyl oxygen. Although in acidic aqueous solutions amines and histidine imidazole rings are preferentially protonated over amide carbonyls, there is less of a difference in basicity in the gas phase. Once in the vacuum of a mass spectrometer, the protons on a peptide ion are relatively free to move about, and this "mobile proton theory" provides an important framework for understanding and predicting how peptides will fragment. An important exception seems to occur when the number of arginine residues exceeds the number of charging protons (Kapp *et al.*, 2003). The guanido group of arginine has such high gas-phase basicity that it tends to sequester protons and makes them unavailable for inducing amide bond fragmentation. In the event that there is no amide protonation, higher collision energy is needed to mobilize the proton on the arginine. The higher collision energy can result in alternative and sometimes unexpected and incomplete fragmentation

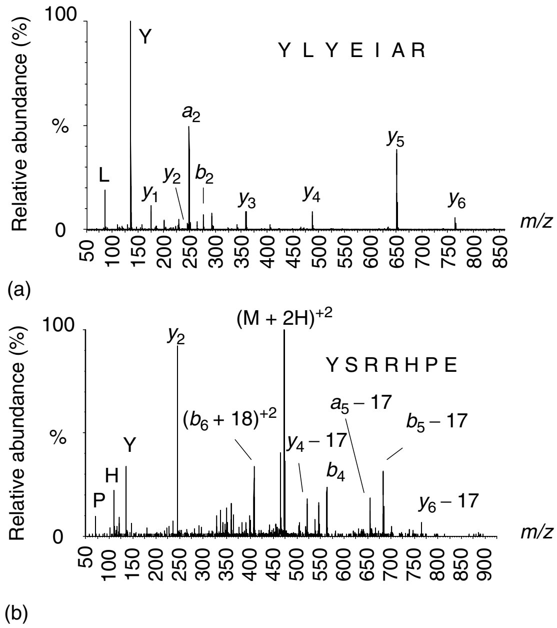

Figure 2 Effect of a mobile proton on peptide fragmentation. (a) A doubly protonated peptide ion containing only one arginine leaves a single mobile proton available for promoting cleavages at amide bonds, as indicated in Figure 1(a). This spectrum exhibits a contiguous series of *y*-type ions that can be easily sequenced. (b) A doubly protonated peptide ion containing two arginine residues, leaving no mobile proton. In this spectrum, there are no contiguous series of ions from which the sequence can be deduced, but there are several unusual fragment ions – doubly charged *b*+18 ions, plus a preponderance of neutral losses from a few *y*-, *b*-, and *a*-type ions

(e.g., Figure 2). The MS/MS spectrum of a doubly protonated peptide ion that contains only one arginine residue (i.e., there is one mobile proton) contains a contiguous series of *y*-type ions and is easily sequenced (Figure 2a). The spectrum of a peptide containing equal numbers of arginines and protons (no mobile proton) exhibits unusual fragment ions that do not delineate the entire sequence (Figure 2b). Electrospray-ionized tryptic peptides tend to produce easily sequenced MS/MS spectra (e.g., Figure 2a), since they typically have no more than one arginine and are usually multiply protonated (i.e., they have a mobile proton). Furthermore, by placing the arginine at the C-terminus, this helps ensure that a complete series of *y*-type ions are formed.

The presence or absence of a mobile proton accounts for some well-known observations. First, cleavage on the C-terminal side of aspartic acid is enhanced for peptide ions lacking a mobile proton (Yu *et al*., 1993; Wysocki *et al*., 2000), which is thought to be due to self-protonation of the amide backbone by the acidic side chain. Second, cleavage on the N-terminal side of proline is enhanced for peptide ions containing a mobile proton (Wysocki *et al*., 2000). This is presumably due to skewing the population of amide protonation to favor N-alkylated amides, which have higher gas-phase basicity (Nair *et al*., 1996). Thus, the N-terminal side of proline is more likely to be protonated, and therefore suffer a cleavage.

3. General approach to sequencing peptides

If a single complete and contiguous series of a single ion type is present in a spectrum, then deducing the sequence is a simple matter of subtracting one fragment ion from the next (e.g., Figure 3). Each mass difference would correspond to one of the amino acid residue masses (Table 1). However, since it is not known if the ion series contains the C- or N-terminus (i.e., whether the series is due to y-type or b-type ions), the directionality of the derived sequence is not known. To determine this, one needs to be able to plausibly connect the series with one of the termini. For tryptic peptides, which have a C-terminal lysine or arginine, this can be done by determining if the lowest mass ion in the series corresponds to a y_1 ion containing either lysine ($y_1 = m/z$ 147) or arginine ($y_1 = m/z$ 175) (Figure 3a). If the peptide is not derived from tryptic proteolysis, then one would look for y_1

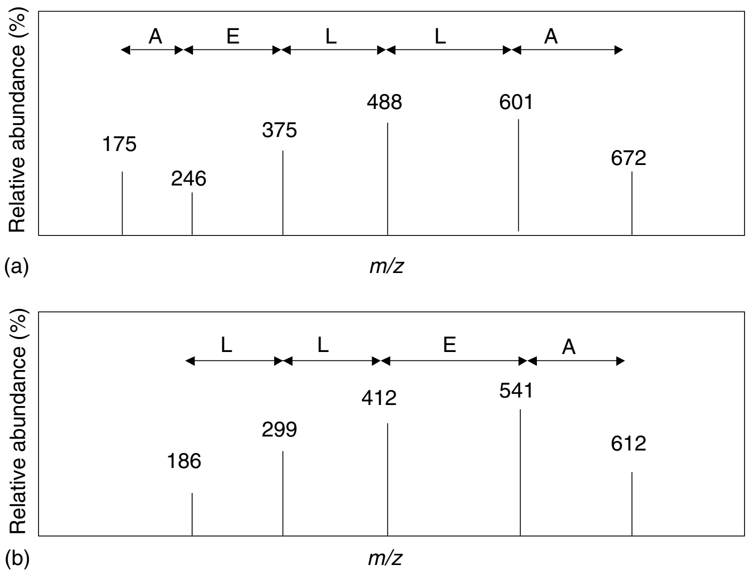

Figure 3 General approach to peptide sequencing. Hypothetical spectra are shown of a peptide with a molecular weight of 785. (a) Fragment ion mass differences delineate a partial sequence; however, the directionality is not known (i.e., the partial sequence could be either AELLA or ALLEA). The lowest mass ion in the series at m/z 175 corresponds to a y_1 ion containing an arginine residue; therefore, a likely explanation is that the series contains the C-terminus – ALLEAR. This partial sequence is 114 Da short of the peptide mass (corresponding to N or two Gs), so two candidate sequences would be NALLEAR or GGALLEAR. (b) The fragment ion mass differences delineate two possible sequences (LLEA or AELL, directionality is unknown). The lowest mass ion in the series does not correspond to any possible y_1 ion ($186 - 19 = 167$, which does not correspond to an amino acid residue mass listed in Table 1). If the ion series was due to b-type ions, then the highest mass ion might be due to the loss of a single C-terminal residue. Subtract 17 Da from the peptide mass and then subtract the highest mass ion in the series ($785 - 17 - 612 = 156$). The residue mass of arginine is 156, so this could be assumed to be a b-type ion series. Hence, a partial sequence can be deduced as LLEAR, which is 185 Da less than the peptide mass. Therefore, there are two or more unsequenced amino acids with a combined mass of 185 Da that is appended to the N-terminus – [185] LLEAR

ions corresponding to any other possible amino acid (y_1 = residue mass plus 19). Alternatively, one can check to see if the highest mass ion in the series is one residue short of accounting for the entire mass of the peptide (e.g., Figure 3b).

Interpreting MS/MS spectra is never as simple as what is depicted in Figure 3. Usually, there is more than one ion series, and, in addition, secondary fragmentations frequently occur (losses of water or ammonia). Internal fragment ions will cause confusion, and sometimes certain y- or b-type ions are missing. For example, it is very common to not observe fragmentation between the two N-terminal amino acids. In these cases, the exact sequence cannot be determined; one can only say that there are two or more amino acids with a certain combined mass that are located at the N-terminus. Additional ambiguity results from the fact that leucine and isoleucine have identical masses and cannot be distinguished. Glutamine and lysine differ by only 0.036 Da, and phenylalanine and oxidized methionine by 0.033 Da. These mass differences can be detected only with higher-mass-accuracy instruments that are well calibrated. Also, one needs to remember that certain pairs of amino acids have similar or identical masses as some single amino acids (G + G = N, A + G = Q, G + V ∼ R, A + D ∼ W, S + V ∼ W). Some of these difficulties are demonstrated in the examples described below.

Different types of instruments will provide data with different characteristics. Two tryptic peptide examples will be shown below – one from an ion trap (Cooks and Kaiser, 1990) and the other from a quadrupole/time-of-flight (Qtof) hybrid (Morris *et al*., 1996). The ion trap that was used in this example exhibited lower resolution (unit resolved) and lower mass accuracy (+/− 0.4 Da); another characteristic of ion trap spectra is that part of the lower mass end of the MS/MS spectrum is absent. In contrast, the Qtof mass spectrometer provided full scans with sufficient resolution and accuracy to distinguish lysine from glutamine. Another difference is that ion trap spectra contain abundant high-mass b-type ions, whereas Qtof MS/MS spectra rarely exhibit b-type ions containing more than a few amino acids.

3.1. *Example #1: ion trap spectrum*

The approach taken in this example (Figure 4) is to first see if there are any partial sequences that can be easily determined from the least noisy region of the spectrum. For MS/MS spectra of multiply charged peptide ions, the least noisy region is located above the precursor m/z value (Figure 4b). In this region, there are two ion series (ions marked * or ˆ); the ion series marked by an asterisk also contains a series due to neutral loss of water. These ion series define two partial sequences – LSLV and LVES – however, the directionality is not known.

Directionality is surmised by trying to connect an ion series to one of the termini by assuming the series is either b-type or y-type (as described in Figure 3). Ion trap MS/MS spectra are missing the lower m/z end, so one cannot expect to find a y_1 ion to help identify the y-type series. On the other hand, high molecular weight b-type ions are frequently observed in ion trap spectra, so the next step is to see if the higher m/z ion from each series will correspond to the loss of arginine or lysine

to form the highest mass *b*-type ion. In this example, the calculation is done by subtracting 17 (the mass of the C-terminal OH group) from the peptide molecular weight (1228, in this example), and then subtracting the highest *m/z* value from each of the two series (thus, $1228 - 17 - 987 = 224$ and $1228 - 17 - 1083 = 128$). The mass difference of 128 Da corresponds to the residue mass of lysine, and so the series marked by an asterisk can now be assumed to be a *b*-type ion series.

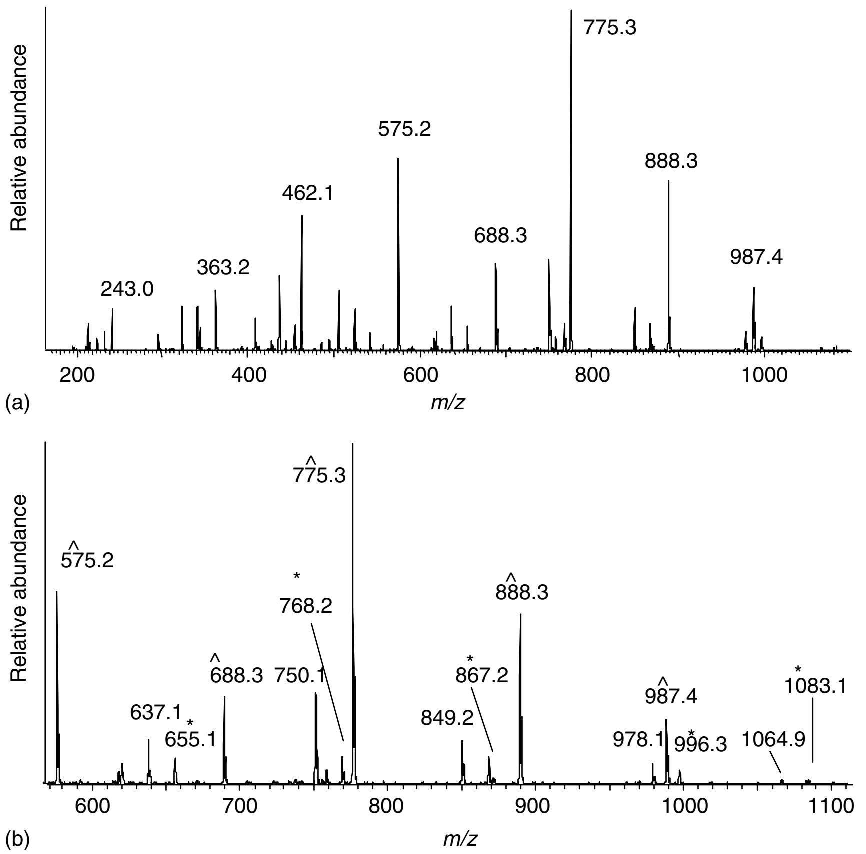

Figure 4 Sequencing a peptide of molecular weight 1228.7 from an ion trap MS/MS spectrum of a doubly charged precursor at *m/z* 615.4. (a) Entire spectrum is shown with a few of the major peaks labeled. (b) The region above the precursor ion *m/z* usually contains the fewest ions and exhibits the simplest fragmentation pattern. One series of ions (labeled ˆ) have mass differences corresponding to the partial sequence LSLV. The other series of ions (labeled *) all have satellite peaks 18 Da lower and delineate a different partial sequence LVES. The ion at *m/z* 1083 has the correct mass for a *b*-type ion resulting from the loss of a single lysine residue; therefore, the ion series marked with an asterisk is hypothesized to be a *b*-type ion series that delineates the partial sequence LVESK. The other series is presumed to be a *y*-type series. (c) From the partial sequence LVESK, the low-mass *y*-type ions (y_1 to y_5) can be calculated (see Table 1) –*m/z* 147, 234, 363, 462, and 575. The ions matching these calculated *y*-type ions are labeled (ˆ), and are contiguous with the similarly labeled (presumed *y*-type ions) in panel (b). The low-mass *b*-type ions can be calculated from the high-mass *y*-type ions (see text) –*m/z* 243, 342, 455, 542, and 655 – which are contiguous with the similarly labeled ions in panel (b)

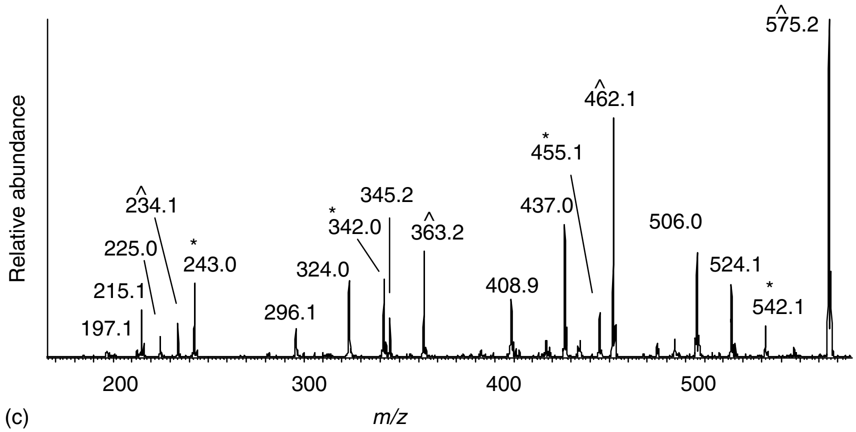

Figure 4 (*continued*)

If no series can be identified as a b-type series, then it is sometimes possible to see if the mass difference obtained could correspond to lysine or arginine plus another amino acid. For example, if m/z 1083 was absent and only m/z 996 was visible (the next ion in the series below 1083), then the mass difference would be 215. Since no combination of lysine or arginine plus another amino acid can equal 224, and since serine plus lysine equals 215, one could still tentatively hypothesize that the asterisk-labeled series is due to b-type ions. In any case, two partial sequences are known at this point – the sequence LVESK (derived from the b-type ion series), plus VLSL located toward the N-terminal part of the sequence (which by the process of elimination is now assumed to be a y-type ion series).

The next step is to connect these two sequences and possibly extend them. From the partial sequence LVESK, the low-m/z y-type ions can be calculated – add 19 to the residue mass of lysine to obtain y_1, add the residue mass of serine to the y_1 mass to get y_2, and so on (Figure 4c). The mass of y_1 is usually below the mass range of an ion trap MS/MS spectrum, and one would not expect to see it. The other y-type ions (y_2 through y_5) are all present. The y_5 ion happens to be the lowest m/z ion in the series that defined the partial sequence VLSL (Figure 4b), which indicates that the two partial sequences are linked (VLSLLVESK). Similarly, low-mass b-type ions can be calculated from the high-m/z y-type ions by adding the mass of two protons to the peptide molecular weight and then subtracting the y-type ion mass (i.e., b-type ions = peptide MW + 2 hydrogen atoms − y-type ion). For example, the lowest mass b-type ion is calculated from the highest mass y-type ion (b-type ion $= 1228 + 2 - 987 = 243$). This b-type ion is composed of more than one amino acid, most likely two; hence, one could tentatively assign the ion at m/z 243 to be b_2. The b_3 through b_6 can be calculated in a similar fashion, all of which are found in the spectrum. The b_6 ion matches the lowest mass b-type ion in the series that defined the partial sequence of LVESK, which helps confirm that the two partial sequences are linked (VLSLLVESK). The only missing piece is at the N-terminal region where there is what is presumed to be a dipeptide of mass 242 Da. This region cannot be sequenced, since there is no b_1 ion or y_{10} ion present.

The sequence, as best can be defined by low-energy CID, is [242]VLSLLVESK, where the number in brackets represents the combined mass of two or more amino acids. Also, the notation "L" implies either leucine or isoleucine, since the two cannot be distinguished.

At this point, one should verify that the majority of fragment ions can be accounted for, given this hypothetical sequence. This is accomplished by checking to see if there are any doubly charged b- or y-type ions, which is done by adding the mass of a proton to the singly charged b- or y-type ion and dividing the sum by two. It is unusual to see multiply charged fragment ions unless the precursor ion had more than two charges, although higher-mass doubly charged y-type ions are sometimes observed from doubly charged precursor ion. Internal fragments (fragments not containing either the C- or N-terminal amino acids) with 2 to 5 residues are sometimes seen, and these m/z values are calculated by summing the amino acid residue masses and then adding a proton. Finally, and most likely, are ions resulting from neutral losses of water and ammonia from the b- and y-type ions. Given these additional fragment ions, plus the y- and b-type fragment ions, all of the major ions can be accounted for, and in fact, the correct sequence is ELVISLIVESK. Losses of water from b-type ions are particularly prominent in this example (Figure 4), which is due to the presence of an N-terminal glutamic acid that readily formed an N-terminal pyroglutamyl N-terminus during the fragmentation process. Similarly, prominent losses of ammonia are seen for peptides with glutamine at the N-terminus.

3.2. *Example #2: Qtof spectrum*

Most tryptic peptides have lysine or arginine at their C-terminus, and the approach taken in this example (Figure 5) is to first see if there are any y_1 ions containing lysine or arginine (m/z 147.113 and 175.119, respectively). The aim is to build the sequence toward the N-terminus in a stepwise fashion. In this approach, the directionality of the sequence is not an issue, since one starts out with what is presumed to be a C-terminal y_1 ion. In this spectrum (Figure 5a), an ion at m/z 147.111 is observed, and therefore a C-terminal lysine is presumed to be present. The mass of the y_1 ion is subtracted from higher-m/z fragment ions in a search for mass differences corresponding to an amino acid residue mass, and two such ions are found at m/z 262.141 (y_1 plus aspartic acid) and 333.177 (y_1 plus tryptophan). Since tryptophan has about the same mass as aspartic acid plus alanine, one could potentially account for both ions by assuming that the penultimate residue is Asp and that the y_2 ion is m/z 262.141. Using the same approach to find y_3 ions, m/z 262.141 is subtracted from higher-m/z fragment ions, and two ions are found at m/z 333.177 and 409.283, corresponding to alanine and phenylalanine. Whereas the mass difference between m/z 333.177 and 262.141 is almost exactly the correct mass for alanine (Table 1), the mass difference between m/z 409.283 and 262.141 is in error by 0.074 Da compared to the correct mass for phenylalanine. For Qtof data, this error is too much, and the y_3 ion is probably m/z 333.177. At this point, likely $y_1 - y_3$ ions have been identified that define a partial sequence at the C-terminal end of the peptide (ADK). Continuing this process, two potential

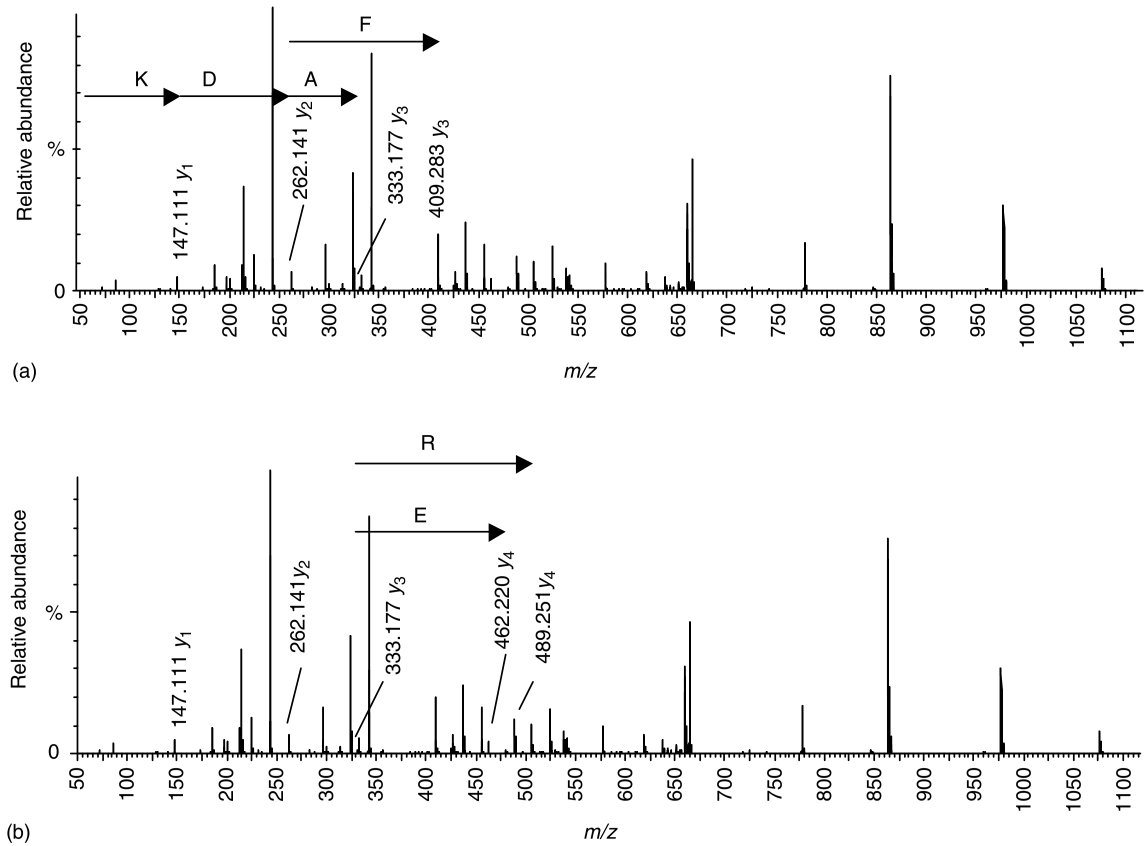

Figure 5 Sequencing a peptide of molecular weight 1317.67 from a Qtof MS/MS spectrum of a doubly charged precursor at *m/z* 659.8. (a) The y_1 ion representing a C-terminal lysine is present at *m/z* 147.111. There are two ions at *m/z* 262.141 and 333.177 that differ in mass from the y_1 ion by an amino acid residue mass (aspartic acid and tryptophan, respectively). Since the residue mass of tryptophan is approximately the same as the combined mass of aspartic acid and alanine, an additional ion is accounted for by assuming that the C-terminal sequence is ADK (y_2 = *m/z* 262 and y_3 = *m/z* 333.177) rather than WK (y_2 = 333.177). The mass accuracy of the Qtof instrument excludes an alternative y_3 ion at *m/z* 409.283. (b) There are two potential y_4 ions; however, for *m/z* 489.251, there are no other ions at higher *m/z* that differ by an amino acid residue mass (i.e., it is a dead end). (c) The putative y_4 ion at *m/z* 462.220 is the low-mass end of a series of ions that unambiguously define a partial sequence containing six amino acids. (d) Most of the remaining ions not hypothesized to be *y*-type ions (as described in panels a–c) are identified as *a*- or *b*-type ions, plus some neutral losses

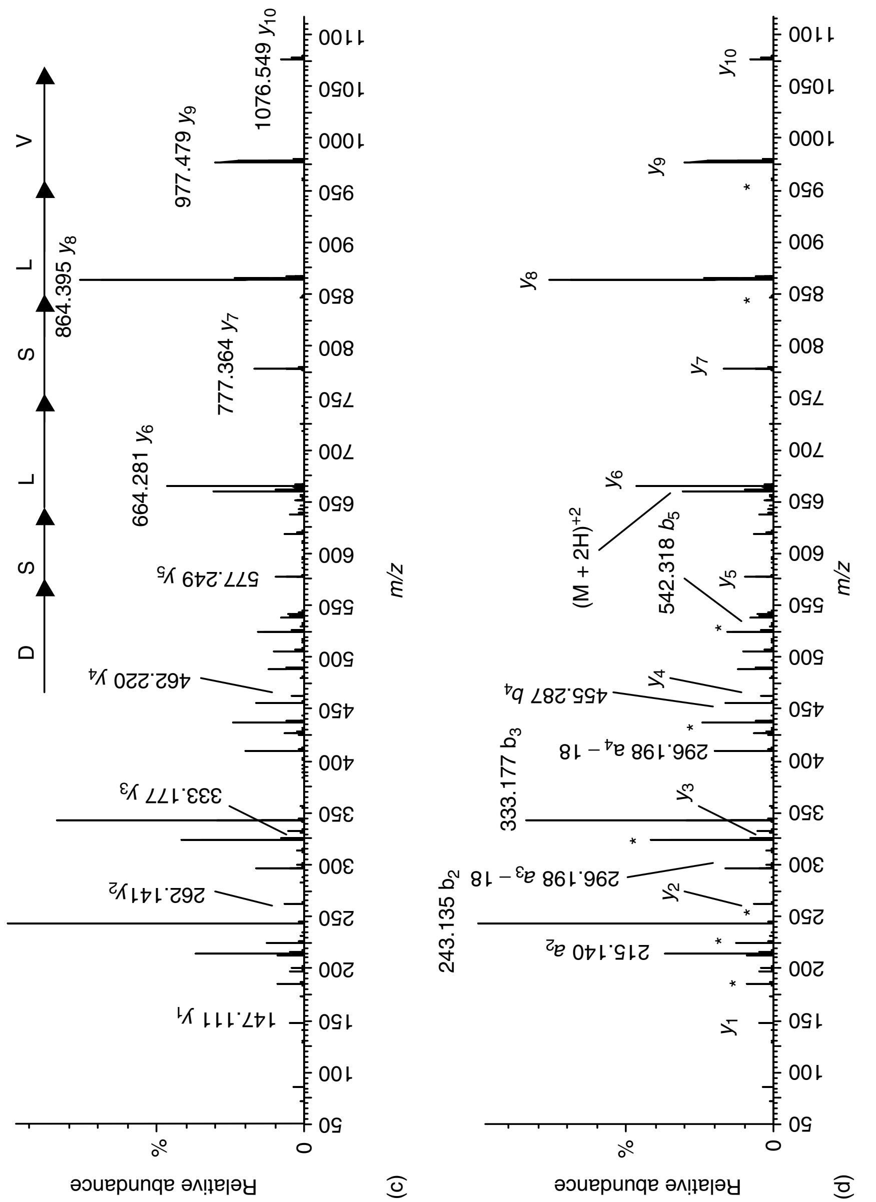

Figure 5 *(continued)*

y_4 ions are identified at m/z 462.220 and 489.251, corresponding to additions of glutamic acid and arginine respectively. The errors in mass differences between these two ions and the y_3 ion at m/z 333.177 are both sufficiently small that it is not possible to choose between the two. Hence, further sequence extensions have to proceed, keeping both possibilities in mind. However, there are no ions above m/z 489.251 whose mass difference corresponds to a single residue. In contrast, the ion at m/z 577.249 is almost exactly the mass of aspartic acid above m/z 462.220. The remainder of the spectrum contains a series of ions from m/z 664.281 to 1076.549 whose mass differences delineate a partial sequence of SLSLV.

From the highest-mass y-type ion at m/z 1076.549, one can calculate a low-mass b-type ion at m/z 243.14 (b-type ions = peptide MW + 2 hydrogen atoms − y-type ion). This b-type ion is composed of more than one residue, most likely two. As in Example #1, the next step is to verify that the remaining abundant ions can be accounted for as either b- or y-type ions, multiply charged ions, internal fragment ions, neutral losses, or immonium ions. Given the limitations of low-energy CID, one can rationally determine the sequence to be [242]VLSLSDEADK, where 242 implies the presence of more than one residue whose residue mass sum is 242. Likewise, L signifies either isoleucine or leucine; however, using the answer to Example #1 as a clue, the reader may be able to correctly guess the entire sequence.

4. Conclusion

Deriving sequences from tandem mass spectra is slow and tedious, but not particularly difficult. Most people have acquired the necessary mathematics skills (addition and subtraction) by the age of eight, although the possibility of multiple charging resulting from electrospray ionization may require more advanced math skills (multiplication and division). The main impediment for most people is that there is not enough time to interpret all the spectra generated. For this reason, there have been a number of attempts to automate the process using various computer programs and algorithms (e.g., Bartels, 1990; Biemann *et al*., 1966; Chen *et al*., 2001; Dancik *et al*., 1999; Fernandez-de-Cossio *et al*., 2000; Ma, 2003); although this is an important topic, further discussion of these programs is beyond the scope of this tutorial.

Specialist Review

FT-ICR

Mark P. Barrow, William I. Burkitt and Peter J. Derrick
University of Warwick, Coventry, UK

1. Introduction

It is Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry (Amster, 1996; Comisarow and Marshall, 1974a,b,c; Jacoby *et al*., 1992; Marshall and Schweikhard, 1992; Marshall *et al*., 1998) which among mass spectrometric methods (*see* Article 10, **Hybrid MS**, Volume 5, Article 7, **Time-of-flight mass spectrometry**, Volume 5, Article 8, **Quadrupole mass analyzers: theoretical and practical considerations**, Volume 5, and Article 75, **Mass spectrometry**, Volume 6) holds the greatest potential at the forefront of research because of the inherently ultrahigh resolution and mass accuracy which can be achieved. FT-ICR mass spectrometry allows unequivocal mass assignment and resolution of species that could not otherwise be distinguished if using some other types of mass spectrometer. This latter capability is particularly relevant for the analysis of multi-component mixtures (Barrow *et al*., 2003; Wu *et al*., 2003b). All varieties of mass spectrometer must involve the analysis of gas-phase ions to obtain a mass-to-charge ratio (m/z) and ion sources must be used to generate the gas-phase ions from a neutral sample. FT-ICR is no different in these respects.

2. Basic principles of FT-ICR mass spectrometry

In FT-ICR mass spectrometry, ions are usually generated externally in a separate ion source and then injected into a container known as the cell (see Figure 1), which is typically cubical or cylindrical in geometry. The cell is located within a strong magnetic field, typically generated using a superconducting magnet. Charged particles moving in the presence of a magnetic field, with a component of their velocity perpendicular to the magnetic field axis, will experience a force known as the Lorentz Force. The axes of this force, motion of the (positively) charged particle, and magnetic field are mutually perpendicular, as dictated by Fleming's Left Hand Rule. A charged particle, such as an ion, will begin to precess about the center of the magnetic field axis, resulting in an orbit. This motion is known as the cyclotron motion. The cyclotron frequency is related to the mass-to-charge

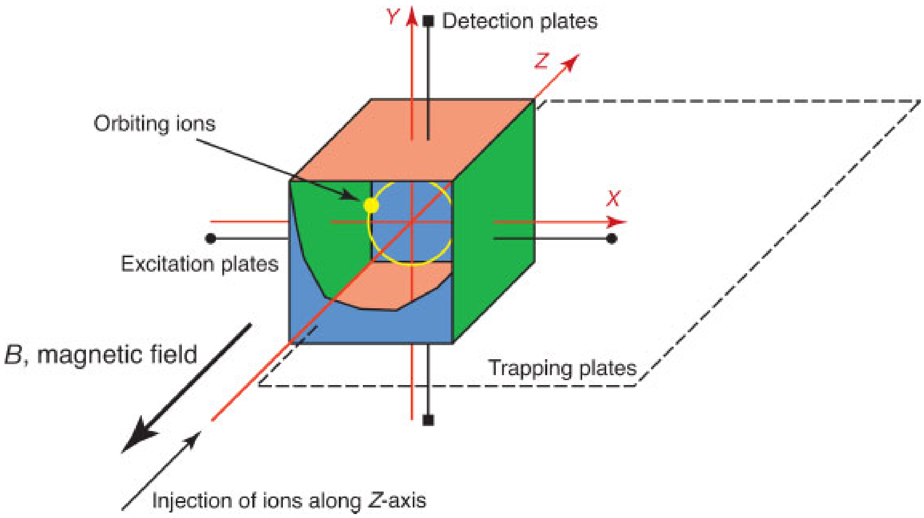

Figure 1 Schematic representation of a cubic FT-ICR cell. The cell is aligned with the bore of the magnet so that the magnetic field axis is coaxial with the trapping axis (z-axis). The excitation and detection plates can be seen, with the trapping electrodes at each end of the cell, and the orbiting ions are shown in yellow

ratio of the ion, as shown in equations (1a) and (1b):

$$\omega = \frac{qB}{m} \tag{1a}$$

$$f = \frac{qB}{2\pi m} \tag{1b}$$

where q is the charge on the ion, B is the magnetic field strength, m is the mass of the ion, ω is the cyclotron frequency in terms of radians per second, and f is the cyclotron frequency in terms of Hertz. Ions of lower m/z have higher cyclotron frequencies than ions of higher m/z.

The FT-ICR cell consists of the two excitation and two detection plates, but, in order to restrain the ions' motion along the axis of the magnetic field, it is necessary to include two trapping plates. A low potential (typically of an order of 1 V) is applied to the trapping plates. When the ions enter the FT-ICR cell, the radii of the cyclotron orbits are too small to be detectable. The ions must therefore be excited to detectable radii and this occurs through usage of a radio frequency (RF) potential applied to two excitation plates operating at the resonant frequency (i.e., resonant with the cyclotron frequency) of the ions. All ions are excited to orbits of the same radii, though their cyclotron frequencies differ. Figure 2 depicts the excitation of ions to a detectable orbit radius. Detection of the ions occurs as the ion packets pass two detector plates. As the ion packets move past these plates, charge moves within the detection circuit to counteract the proximity of the ions. This current can be measured as a function of time and it is from here that the raw data (known as a transient, time-domain data, or sometimes as a free induction decay or FID) is

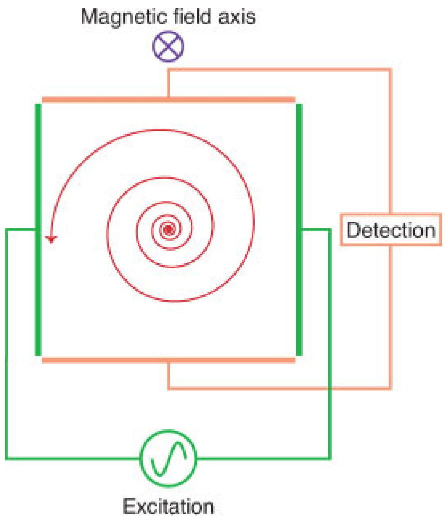

Figure 2 A cross section of a cubic FT-ICR cell, depicting excitation of ions (in red) through the application of an RF potential to the excitation electrodes. Once the ions have been excited to a cyclotron motion of suitable radius, the image current of the orbiting ions can be detected on the detection plates

obtained. It should be noted that the ions are remeasured because of the fact that they repeatedly pass the detector plates, as nondestructive detection is employed.

The raw data will represent the detection at the same time of all the ions, with their different cyclotron frequencies. Information about the ion packets' frequencies is obtained through usage of the mathematical procedure known as a Fourier transform (FT) (Marshall and Comisarow, 1975; Marshall and Verdun, 1990) by which frequency information is obtained from time-domain data. A spectrum is produced where signal intensity is plotted as a function of the cyclotron frequencies of the ions present. From equations (1a) and (1b), it can be seen that the cyclotron frequency is related to m/z. It is therefore possible to convert the plot and to perform a calibration (Shi *et al*., 2000), thereby creating a mass spectrum in which signal intensity is plotted as a function of m/z. The conversion of raw data to a mass spectrum using a Fourier transform is depicted in Figure 3.

3. Advantages of FT-ICR mass spectrometry: mass accuracy and resolution

The excellent mass accuracy and resolution of FT-ICR mass spectrometers are amongst the technique's strongest assets. Mass accuracy is a measurement of how well the observed m/z correlates with the theoretical value. Many other types of modern commercial mass spectrometers cite specifications for mass accuracy of the order of tens of ppm over a specific mass range, whereas specifications for FT-ICR mass spectrometers typically cite mass accuracies of 1 ppm or better (lower). Equation (2) is the relationship for determining the mass accuracy of a result when

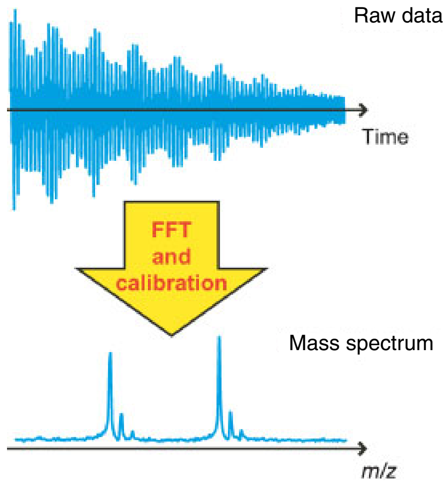

Figure 3 Schematic diagram showing the measured data of a FT-ICR experiment and the subsequent fast fourier transform (FFT) and calibration of the measured data into the final mass spectrum

comparing the observed m/z with the value believed to be "true," called here the theoretical m/z:

$$\text{Mass accuracy} = \frac{m_{\text{observed}} - m_{\text{theory}}}{m_{\text{theory}}} \times 1000000 \qquad (2)$$

m_{observed} is the m/z of the peak of interest in the mass spectrum obtained and m_{theory} is the theoretical m/z that would have been expected for the species. The mass accuracy is defined in terms of ppm (equation 2).

Resolution is extremely important for resolving closely spaced signals, such as in the cases of multiply charged ions (as generated by electrospray ionization, for instance). The ability to use instruments with high resolution can sometimes make the difference between identifying and not identifying a species of interest. Equation (3) defines the resolution:

$$\text{Resolution} = \frac{m}{\Delta m} \qquad (3)$$

where m is the m/z of the peak of interest and Δm is the width, in terms of m/z, determined using any one of the many methods of mass spectrometry. Resolution can be measured using the "10% valley" definition, as most commonly applied when using magnetic-sector instruments, or by using the full width at half maximum (FWHM) definition, which is typically used during the analysis of data acquired from time-of-flight (TOF) (*see* Article 7, **Time-of-flight mass spectrometry**, Volume 5) or FT-ICR mass spectrometers, illustrated in Figure 4. FT-ICR mass spectrometers can routinely reach resolutions of hundreds of thousands in "broadband mode" ("normal" experimental conditions) or even reach a resolution of a few million in "heterodyne mode" (where a very narrow

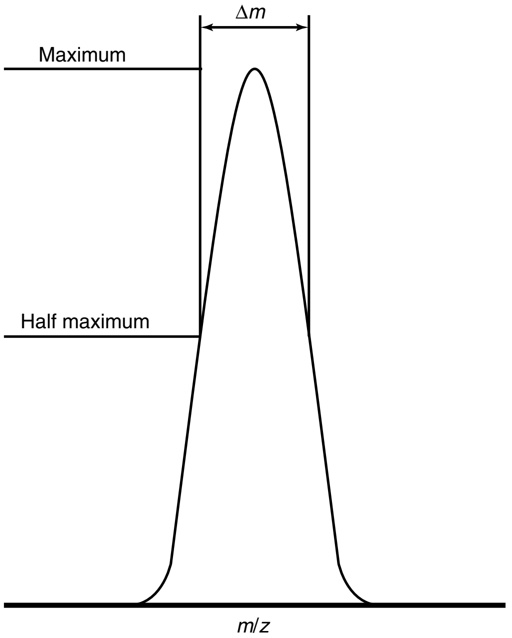

Figure 4 Definitions of resolution, showing the "full width at half maximum" definition, which is most typically used in conjunction with time-of-flight and FT-ICR mass spectrometers

m/*z* range is studied but under very high-resolution conditions), compared with commercial time-of-flight mass spectrometers approaching approximately 10 000 and commercial magnetic-sector mass spectrometers approaching a resolution of 100 000.

4. Electrospray ionization

Electrospray ionization (ESI) (Dole *et al*., 1968; Fenn *et al*., 1989; Mann, 1992; Yamashita and Fenn, 1984a,b) is the ionization technique nowadays most frequently coupled with FT-ICR mass spectrometry. ESI has the advantage of minimizing fragmentation, which is particularly important for labile biological molecules, where fragments must not interfere with the mass spectrum when trying to determine the original constituents. ESI frequently leads to the formation of multiple charged ions, particularly in the case of large macromolecules. As mass spectrometry is based upon the determination of *m*/*z*, not mass alone, it is frequently the case that a mass spectrum will contain the same molecules but in a variety of charge states, and therefore at several different *m*/*z* values. As ions become more highly charged, the *m*/*z* becomes lower and the spacing between the "isotopomers" (peaks due to the presence of other isotopes) becomes narrower. As a result, it becomes more difficult to resolve the signals and the resolution of the mass analyzer becomes more important. Note that the charge state of an ion can be determined by examining the spacing between the isotopomer signals. The growth of electrospray

ionization can, therefore, be seen to be promoting the growth in FT-ICR mass spectrometry, for FT-ICR mass spectrometers offer the ultrahigh resolution that is particularly well suited to a coupling with ESI. For these reasons, ESI FT-ICR mass spectrometry has become increasingly important for the study of biological molecules in recent years.

5. Tandem mass spectrometry techniques

For structural elucidation, "tandem mass spectrometry" (*see* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5) experiments are performed, in which particular ions can be selected and dissociated. The resulting dissociation pattern provides structural information. One of the most common forms of tandem mass spectrometry experiment performed on FT-ICR mass spectrometers is sustained off-resonance irradiation collision-induced dissociation (SORI-CID) (Amster, 1996; Laskin *et al*., 2000; Palmblad *et al*., 2000). SORI-CID is based upon multiple collisions of the selected ions with gas particles, resulting in a "slow heating effect" and the ions' internal energies are increased, leading to dissociation. Other varieties of tandem mass spectrometry experiment include infra-red multiphoton dissociation (IRMPD) and electron capture dissociation (ECD). IRMPD (Stace, 1998; Tsybin *et al*., 2003) entails the usage of a laser, most commonly a CO_2 laser, to irradiate ions whilst trapped in the cell, and can be compared with the "slow heating effect" of SORI-CID. IRMPD has the advantage of avoiding the requirement to put a collision gas into the cell, as a higher pressure leads to a more rapid damping of the transient (time-domain data) and therefore decreases the resolution. SORI-CID and IRMPD are usually considered to be ergodic processes (Derrick *et al*., 1995), where the weakest bonds are cleaved. When studying peptides and proteins, backbone amide bonds and posttranslational modifications, tend to be cleaved, leaving to the formation of b-fragments and y-fragments from peptides and proteins (Sheil *et al*., 1990). ECD (Zubarev *et al*., 1998, 1999; Zubarev, 2003) involves a beam of low-energy electrons (0.2 eV or less, for instance) being emitted into the cell. Ions capture these low-energy electrons and dissociation occurs. The dissociations are thought to be nonergodic processes. With peptides and proteins, N–C and S–S bonds are preferentially cleaved. Utilization of ECD leads primarily to the formation of c and $z^\bullet$ fragment ions, and one advantage is that noncovalent bonds and phosphorylation sites (*see* Article 61, **Posttranslational modification of proteins**, Volume 6, Article 63, **Protein phosphorylation analysis by mass spectrometry**, Volume 6, and Article 73, **Protein phosphorylation analysis – a primer**, Volume 6) are left intact. ECD mass spectra can therefore be relatively less complex due to avoidance of unwanted fragmentation.

Fourier transform ion cyclotron resonance mass spectrometry represents an increasingly powerful tool for the study of biological molecules, especially within the context of "proteomics" (*see* Article 2, **Sample preparation for proteomics**, Volume 5) (Aebersold and Mann, 2003; Sali *et al*., 2003; Tyers and Mann, 2003). An example of a mass spectrum of a biological sample, in this case the protein known as ubiquitin, is shown in Figure 5. FT-ICR mass spectrometry, in particular, offers the greatest potential for the analysis of complex mixtures such as enzyme

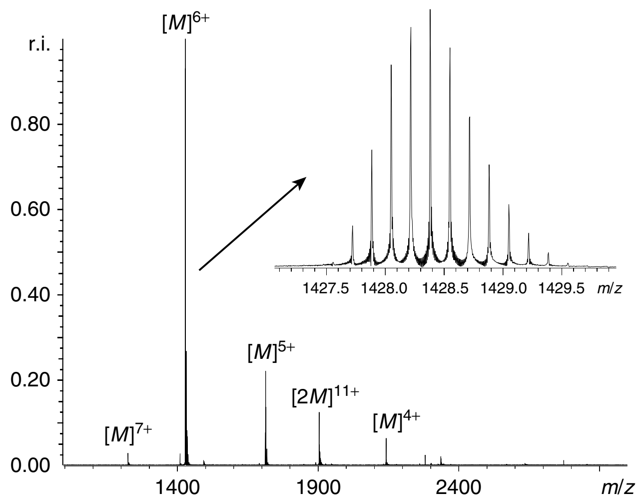

Figure 5 ESI FT-ICR mass spectrum of 20-µM ubiquitin in an aqueous 10-mM ammonium acetate solution, measured in terms of relative intensity versus m/z. The ubiquitin ions are measured in the mass spectrum in a number of charge states, there were also some noncovalently bound ubiquitin ions present. The inset shows a closeup of the ubiquitin ions in the 6+ charge state, the isotopomers were clearly resolved

digest owing to its inherently high mass accuracy, resolving power, and dynamic range (Wu, 2003a). These attributes allow for the positive identification of a greater number of species within a mixture than is possible with other mass spectrometric techniques, including species of low abundance such as posttranslationally modified proteins. However, with the advent of the low-excitation ionization afforded by ESI, mass spectrometry has increasingly been used for the characterization of the solution-phase properties of biomolecules. The ability to disperse into the gas-phase and ionize noncovalent complexes has allowed for the study protein–protein and protein–ligand interactions (Loo, 1997). The high resolution and mass accuracy of FT-ICR mass spectrometry offers decisive advantages when studying such interactions. For example, the ability of FT-ICR to resolve the isotopes of proteins up to 100 kDa in mass (Kelleher *et al*., 1997) allows the definitive determination of the oligomeric state of a protein, or the ligands binding to a particular complex to be decisively determined. The structural characterization of such complexes is currently being attempted using tandem mass spectrometry techniques such as SORI-CID and ECD. Increases in sensitivity of detection and magnetic field strength will only serve to increase the potential of FT-ICR mass spectrometry to allow the understanding of life at the molecular level.

Specialist Review

Laser-based microdissection approaches and applications

Rosamonde E. Banks
University of Leeds, Leeds, UK

1. Introduction

There is considerable heterogeneity in terms of both the numbers and types of cells present in different organs or tissues, reflecting their different biological functions. As an example, the cellular composition of the kidney comprises many diverse cell types including proximal tubule epithelial cells, distal tubule epithelial cells, collecting duct epithelial cells, endothelial cells, podocytes, mesangial cells, fibroblasts, and muscle cells. The proteome of any tissue, therefore, is actually a composite, reflecting the proteome of all its constituent cell types. The cellular makeup of tissues or organs can vary, however, not only during pathological states but also as a result of normal physiological changes. A prime example of this is the profound cellular changes that occur in the ovary and endometrium during the menstrual cycle. With diseases such as cancer, much of the normal tissue architecture may be lost with tumor areas consisting largely of malignant cells, but containing increased numbers of endothelial cells and infiltrating lymphocytes as part of the pathology. Additionally, within such a tumor and the surrounding tissue, cells that are at different stages of genetic evolution may be present, representing the transition from normal to frankly malignant and invasive pathology, and different microenvironments may be present, for example, normoxic and hypoxic areas.

Such tissue heterogeneity undoubtedly impacts on comparative studies, introducing more background "noise" to the analysis than would be present if the diseased cells alone were compared with their normal counterpart. The ability to isolate specific cell types or areas for experimental analysis would overcome this and generate more easily interpretable and readily applicable data. Conversely, however, while analysis of whole-tissue lysates may be more difficult to interpret, it does involve minimal manipulation of the in vivo state and the interplay between different elements of tissue, such as stromal–epithelial and endothelial–epithelial interactions, are undoubtedly important. The relative merits of either the whole-tissue approach or the selection of specific cells should be taken into account and the most appropriate method determined by the specific questions being addressed.

In terms of enriching for defined cell populations, various manual microdissection, immunoisolation, or primary cell culture generation strategies have been

explored. However, all these have inherent problems ranging from the laborious nature of the work to the possibility of introducing in vitro artifacts. One recent area of technological development that has facilitated the isolation of specific cell types or cellular areas without enzymatic digestion or cell culture is that of laser-based microdissection systems. Used extensively in experiments involving subsequent analysis of DNA or RNA from the isolated cells, the numbers of reports of successful use in proteomics-based studies are far fewer but nevertheless show the potential of the approach. The principles underlying the various laser-based microdissection instruments are outlined below, together with a consideration of the technical issues, and their use in various proteomics-based research illustrated.

2. Principles of laser-based microdissection systems

There are three main commercially available systems in current use. The first developed was the PixCell laser capture microdissection (LCM) system, which was developed by scientists at the National Institutes of Health in the United States (Emmert-Buck *et al*., 1996) and is marketed by the bioengineering company Arcturus. The system is based on a high-precision inverted microscope with a low energy, near-infrared laser mounted above it, a manipulator arm, and a computerized laser control and image capture platform. Using normal cleaned glass slides, the tissue section to be dissected is fixed and stained using appropriate protocols and the slide is placed on the microscope platform. A 6-mm-diameter Perspex cap, whose lower surface is covered with a transparent thermolabile ethylene vinyl acetate film, is then lowered into place onto the section with the film in direct contact with the tissue. By moving the stage so that the area of interest is in the field of view and by focusing the laser beam of adjustable diameter 7.5 to 30 μm through the cap onto an area containing cells of interest, the laser is then fired and the heat generated causes localized melting of the film and fusion with the selected cells directly below. The combination of relatively low energy and short-duration pulses (up to 5 ms) minimizes the heat damage to the tissue. Using the micromanipulator arm, the cap is then subsequently lifted from the section, complete with the fused dissected cells (Figure 1). Captured cells can then be solubilized using an appropriate extraction buffer either immediately or following further dissection and collection of cells. The most recently developed version of this system allows much of the process to be automated once appropriate areas of tissue are selected on the section image.

The PALM MicroBeam system couples “laser microbeam microdissection” (LMM) to ablate areas of tissue surrounding the cells of interest with “laser pressure catapulting” (LPC) to subsequently retrieve the selected area of cells (Schutze and Lahr, 1998). Again, the system is based around an inverted microscope to visualize the tissue section with the microdissection, that is, the movement of the stage and laser firing being automated. The operator delineates essentially the area containing the cells of interest on a computer screen and the process of ablation of the surrounding area is then computer-controlled. This strategy is therefore noncontact and nonheating, with cells of interest being cut round using cold photolysis generated by an ultraviolet N_2 laser microbeam rather than positively

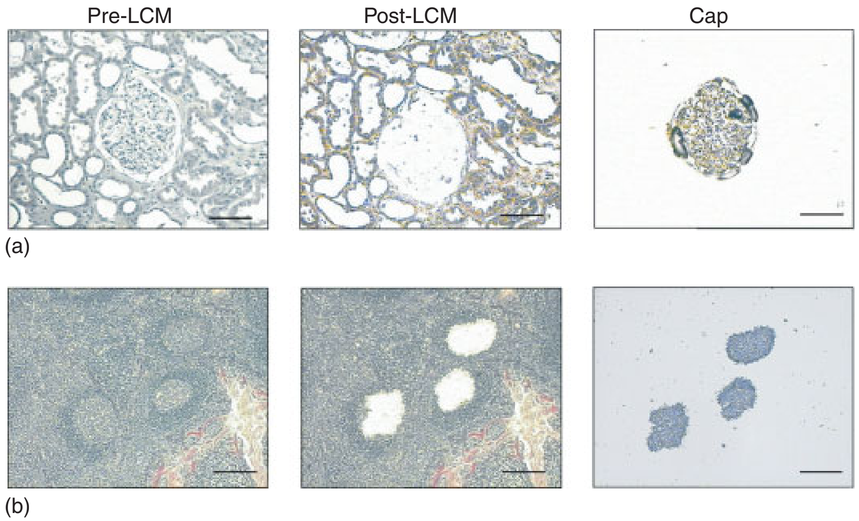

Figure 1 Examples of laser capture microdissection of (a) a renal glomerulus from kidney and (b) germinal centers from lymphoid tissue. Shown are the appearance of the tissue prior to and following capture and the captured cells present on the cap. The bar represents 100 µm (Reproduced from Banks, Dunn, Forbes, Stanley, Pappin, Navan, Gough, Harnden, and Selby, 1999, by permission of Wiley VCH)

targeted. The minimum width of the laser track separating adjacent areas is quoted as $<1\,\mu m$, thus allowing quite selective ablation and delineation of infiltrating cells within areas of interest. To support the section and to allow subsequent visual examination of the retrieved material, a polyethylene naphthalate membrane backing is often used between the section and the glass slide. After microdissection, the laser is used to catapult the dissected tissue, complete with support membrane, into a collecting tube containing appropriate extraction buffer, a process termed *laser pressure catapulting*.

The most recently developed commercially available system is the Leica AS LMD. Similar in principle to the PALM system in that it employs a similar UV laser ablative microdissection strategy to remove surrounding tissue, it has a stated minimum diameter cut of $<2.5\,\mu m$. However, the microscope is a conventional upright version and the slide is inverted such that the dissected material, once freed from surrounding tissue, is collected in a tube below the section, largely under the force of gravity (Kolble, 2000). Again the system is automated in that the operator delineates the dissection area, and in this case the stage remains still with the laser being moved and fired, a process controlled by the computer, to achieve the required ablation of surrounding areas.

3. Technical issues

The relative technical merits of the three systems with particular regard to resolution, ease of use and environment requirements, and sample visualization

have been recently reviewed (Cornea and Mungenast, 2002). Particular issues pertaining to sample processing are briefly discussed below.

The predominant use of laser-based microdissection has been for the study of nucleic acids in selected cell populations, combined with a variety of downstream analytical techniques. The analysis of nucleic acids has the major advantage of requiring very little starting material due to the use of PCR amplification so that single-cell analysis is achievable. Additionally, paraffin-embedded, formalin-fixed material can often be used, allowing better visualization of the microdissection and providing access to a wealth of archival material. The uses of laser-based microdissection with nucleic acids have been reviewed and will not be covered further here (see Further reading).

As there is no amplification equivalent to PCR for proteins, proteomic analysis techniques that can be employed with microdissected material are dependent on a balance between their sensitivity and the time taken to accumulate sufficient material. For example, the dissection required to procure sufficient cells for large format 2D-PAGE requires tens of thousands of shots, which may represent several days of dissection, and there is a question, even with tissues that are relatively easy to dissect, as to whether, generally, only the most abundant protein species will therefore be examined. Those tissues requiring extensive microdissection will also inevitably result in a degree of compromise in terms of the purity achieved, and the degree of enrichment afforded in the protein profile relative to the starting material will also vary between tissue types (Craven *et al*., 2002).

Material fixed in cross-linking agents such as formalin is not suitable for proteomic investigation and hence frozen sections are used, although unfortunately of poorer morphology, particularly when viewed with inverted optics. Tissue sections need to be stained using protocols designed to allow good visualization but minimizing artifacts such as protein degradation and allowing subsequent analysis of extracted proteins. The initial "proof of principle" demonstration used a modified rapid hematoxylin and eosin staining method with proteinase inhibitors on frozen kidney and cervical tissue and showed that material collected by LCM could generate 2D-PAGE (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5) protein profiles, with minimal effects of processing on either the profile or the subsequent mass spectrometric (MS; *see* Article 31, **MS-based methods for identification of 2-DE-resolved proteins**, Volume 5) sequencing results (Banks *et al*., 1999). Since this initial report, the examination of different tissue-processing regimens indicate that the type of fixative for the frozen sections is critical, with ethanol being the preferred option; various stains including hematoxylin and eosin, and methyl green and toluidine blue can be adapted and used successfully, as can the modified immunolabeling protocols using silver-enhanced gold labeling or fluorescent labeling (Craven *et al*., 2002; Mouledous *et al*., 2003a; Ahram *et al*., 2003). More recently, the process of "navigated LCM" has been used, which incorporates the use of fixed unstained sections for the microdissection, thus avoiding staining artifacts, but relies on images generated from adjacent stained coverslipped sections with consequent improved visualization of tissue architecture to delineate and guide the dissection process (Mouledous *et al*., 2003b).

4. Selected examples of applications in proteomics

The majority of published proteomics-based studies using laser-based microdissection have utilized the PixCell LCM system unless indicated otherwise. The different studies are described below, subdivided on the basis of the subsequent proteomic techniques used to analyze the dissected material.

4.1. *Two-dimensional polyacrylamide gel electrophoresis (2D-PAGE)*

One of the main separation techniques is 2D-PAGE. The use of 2D-PAGE (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5) with protein lysates generated from the use of LCM provides a very encouraging endorsement of the approach, with the caveat that there are limitations with respect to sample and tissue type in terms of the degree of enrichment achieved (Craven *et al*., 2002). The initial demonstration of this combination of approaches showed the feasibility of using cells dissected from frozen tissue sections subjected to brief fixation and hematoxylin and eosin staining, with only modest effects of processing on the protein profile and compatibility with subsequent MS sequencing (*see* Article 31, **MS-based methods for identification of 2-DE-resolved proteins**, Volume 5) (Banks *et al*., 1999). As described previously, several other studies have also since explored other technical aspects of tissue processing. The main limiting factor with 2D-PAGE is the amount of material required, which may necessitate tens of thousands of laser shots and microdissection times of several hours or even days depending on the tissue type and still result in only a few hundred spots, that is, far less than normally visualized on large format gels. Inevitably, therefore, even with tissues that are relatively easy to dissect, only the most abundant protein species are likely to be examined.

In the first comparative analysis of microdissected normal versus malignant cells, analysis of lysates generated from approximately 50 000 cells from each matched sample from two patients with esophageal cancer allowed visualization of almost 700 proteins, with 98% similarity between normal and malignant protein profiles (Emmert-Buck *et al*., 2000). Ten proteins were tumor-specific with seven other proteins only found in normal epithelium, one of which was identified as annexin I. Using a combination of Western blotting of microdissected cell lysates and immunohistochemistry, an extension of this study confirmed complete loss or dramatic reduction of annexin I expression in both esophageal and prostate cancers, occurring even at the premalignant stage (Paweletz *et al*., 2000b). This study illustrates the use of a small number of gels requiring large amounts of microdissected protein as the initial step to determine differentially expressed proteins and then validating on a larger sample set using Western blotting with the necessity for much less material. A similar later study on prostate cancer found six tumor-specific changes in two cases examined, one of which was the tumor marker PSA, and which were only present in the microdissected epithelial

compartments but not in stroma (Ornstein *et al*., 2000b). An extension of this study to an examination of 12 matched normal and high-grade tumor samples from 8 patients with cells obtained by LCM or manual microdissection and loading 100 000 to 140 000 cells per gel revealed 40 tumor-specific differences. However, disappointingly, only six of these were present in more than one case. Several of the proteins had been implicated before in tumor biology, for example, the 67-kDa laminin receptor and lactate dehydrogenase. (Ahram *et al*., 2002).

Similar success has also been seen with other cancers such as breast, ovarian, and pancreatic cancers. Examination of six matched pairs of normal breast ductal cells and ductal carcinoma in situ at either the whole tissue level or following LCM with up to 100 000 cells per gel identified 57 proteins to be differentially expressed and which met various criteria including being consistent between samples (Wulfkuhle *et al*., 2002). Only four proteins were identified by both whole tissue – and LCM-based approaches. Using a similar strategy, the 52-kDa FK506 binding protein, RhoGDI, and glyoxalase I were demonstrated to be uniquely overexpressed in invasive ovarian cancer compared with the low malignant potential ovarian tumors (Brown Jones *et al*., 2002), with downstream validation by a combination of Western blotting and reverse-phase protein arrays. In pancreatic cancer, microdissection and the subsequent 2D-PAGE analysis revealed about 800 spots per gel, with nine spots consistently differentially expressed including S100A6, trypsin, and annexin III (Shekouh *et al*., 2003).

The possibility of using fluorescence 2D-difference gel electrophoresis (DIGE; *see* Article 25, **2D DIGE**, Volume 5) has been explored, which avoids the difficulties of gel–gel comparisons and allows more ready identification of spots from parallel gels for sequencing. Using limiting labeling, in a comparison of 250 000 cells from a matched tumour-normal esophageal sample, 1000 to 1100 protein spots were visualized (Zhou *et al*., 2002), with 58 proteins upregulated by >3-fold in tumors and 107 proteins downregulated by >3-fold. Using a matched SYPRO Ruby stained gel (*see* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5), annexin I was identified again as being downregulated and the tumor rejection antigen gp96 was upregulated, both of which were confirmed by Western blotting. Using a similar approach but with saturation labeling, normal murine intestinal epithelium and adenoma tissues from Min mice were compared (Kondo *et al*., 2003). Using only 2.7 to 6.6 µg of protein, which represented a 1-mm^2 area of tissue dissected using the Leica LMD system from a 10-µm-thick frozen section with a collection time of 1 min, a 24-cm 2D-PAGE profile with 1500 spots was generated, 37 of which differed. Using a murine cell line run in parallel to generate sufficient material for MS analysis and subsequent Western blotting for validation, a number of proteins were identified including prohibitin, which is a putative tumor suppressor, HSP84, and a number of 14-3-3 zeta forms.

4.2. *Western blotting*

Western blotting of microdissected material provides not only information about the cellular localization of a protein but also confirmation of its molecular size,

and, depending on antigen and antibody, requires relatively small amounts of material. Examples include the detection of actin, major vault protein, GAPDH, aldolase isoforms, pyruvate kinase, RhoGDI, annexin I, and gp96, with numbers of microdissected cells varying from approximately 250 to 40 000 (Craven and Banks, 2002; Unwin *et al*., 2003; Zhou *et al*., 2002; Paweletz *et al*., 2000b; Brown Jones *et al*., 2002; Wulfkuhle *et al*., 2002). Illustrating the potential of the approach not only in validating identified potential new markers but also in addressing questions regarding known proteins, microdissected material from benign and malignant prostatic epithelium was used to demonstrate that the vast majority of intracellular PSA exists in the free unbound form, but has the capability of binding to α_1-antichymotrypsin form once outside the cell (Ornstein *et al*., 2000a).

4.3. *Immunoassay*

With the increasingly sensitive immunoassays employing chemiluminescent detection, laser-based microdissection represents a source of material for assay. Immunoassay of the amounts of the tumor marker prostate-specific antigen (PSA) in normal and malignant prostate epithelium using only several tens to hundreds of microdissected cells acquired in <15 min, showed that malignant cells were found to contain up to sevenfold more PSA than normal epithelial cells, although there was overlap between the sets (Simone *et al*., 2000). Calculation of the actual number of PSA molecules per cell resulted in estimates of average values ranging from 10 000 to 1 000 000. More recently, hepatitis C virus core protein has been quantified by immunoassay in lysates prepared from microdissected liver cells prepared using the Leica LMD system and found to vary from 7 to 56 pg/cell in infected samples, being more sensitive than immunohistochemistry (Sansonno *et al*., 2004).

4.4. *Multiplex protein and antibody microarrays*

The development of protein microarrays (*see* Article 24, **Protein arrays**, Volume 5, Article 32, **Arraying proteins and antibodies**, Volume 5, and Article 33, **Basic techniques for the use of reverse phase protein microarrays for signal pathway profiling**, Volume 5) enabling the simultaneous high-throughput profiling of many proteins in large numbers of samples, with only relatively small amounts of sample being required, is an area of considerable activity. Various formats exist including ones essentially analogous to cDNA arrays but with either antibodies or ligands arrayed onto which labeled tissue lysates can be applied. Alternatively, tissue lysates are arrayed, which are then probed with antibodies. It is increasingly evident that microdissected cell lysates are suitable for such applications.

Using a reverse-phase array approach, solubilized microdissected prostate tissue has been spotted onto nitrocellulose slides to generate microarrays containing up to 1000 tissue lysate spots/slide. Typically, these were produced using lysates resulting from only 500 to 3000 laser shots (equivalent to 2500–15000 cells). By using lysates from prostate cells covering the transition from normal epithelium

through prostate intraepithelial neoplasia (PIN) to invasive cancer and by probing with a range of antibodies, changes during tumor progression were shown. These included decreased levels of cleaved poly(ADP-ribose) polymerase (PARP) and cleaved caspase-7, increased phosphorylation of Akt, but decreased phosphorylation of Erk and were interpreted as representing activation of prosurvival events (Paweletz *et al*., 2001). Results using antibodies against additional phosphorylated cell signaling molecules provided further evidence of activation of the Akt pathway (Grubb *et al*., 2003). A similarly designed study examining the activation status of several key signaling molecules involved in cell survival and proliferation in microdissected ovarian cancer also found changes in many of the variables examined but with generally no type or stage-specific patterns (Wulfkuhle *et al*., 2003). This may support the need to individualize patient samples in terms of the biological changes and the structuring of therapeutic strategies accordingly.

Antibody arrays have also been used to analyze microdissected samples. Using biotinylated extracts from 2500 to 3500 cells (approximately 0.5 µg) of both stromal and epithelial elements of squamous cell carcinoma of the oral cavity, together with an array containing 368 different antibodies against a variety of proteins, multiple protein differences were found with 11 proteins consistently changing in either relative levels or state of phosphorylation. Several of these were proteins involved in signal transduction pathways, with many exhibiting selective changes in either the epithelial cells or the stroma (Knezevic *et al*., 2001). This illustrates the importance of stromal–epithelial cell interactions in cancer.

4.5. Mass spectrometry

Although more conventionally used for protein identification on the basis of peptide mass fingerprints (*see* Article 3, **Tandem mass spectrometry database searching**, Volume 5), matrix-assisted laser desorption ionization mass spectrometers equipped with time-of-flight detectors (MALDI-TOF; *see* Article 7, **Time-of-flight mass spectrometry**, Volume 5) are increasingly being used to generate profiles of intact proteins or fragments in complex biological samples in the context of disease-specific patterns, requiring only small amounts of protein. Using MALDI-TOF, direct analysis of 1250 cells from normal stroma, normal epithelium, carcinoma in situ, and invasive carcinoma prepared from a mastectomy sample and following addition of sinapinic acid to the LCM film immobilized on a standard stainless steel MALDI target generated distinct reproducible spectra containing 20–50 peaks from four cell types (Palmer-Toy *et al*., 2000). A subsequent investigation examined a range of factors and their effects on the quality of the profile generated, including section staining, ethanol treatment, and matrix application and showed that under optimal conditions, good quality profiles of at least the more abundant peaks could be generated from as few as 10 cells and again demonstrated that this approach could define distinct differences in profiles between normal and invasive breast epithelium (Xu *et al*., 2002).

Several studies have used the SELDI (surface-enhanced laser desorption and ionization) system developed by Ciphergen Biosystems (Fremont, CA, USA) to profile laser microdissected material. Based around a MALDI-TOF MS,

proteins from complex mixtures are immobilized onto ProteinChip arrays containing 8–24 sample spots, by selective capture using the conventional chromatographic chemistries of the chip surfaces. The first study to use SELDI-MS (surface-enhanced laser desorption and ionization-mass spectrometry) to analyze microdissected material was part of a larger study examining the specific forms of several prostate cancer markers in tissue samples and biological fluids. Using only 2000–3000 cells, several proteins were found to be differentially expressed between normal and malignant samples with a peak detected only in the prostate carcinoma samples being found to have the same molecular weight as purified prostate-specific membrane antigen (PSMA) (Wright *et al*., 1999). Several studies have now shown that microdissected material can be examined in this way to discriminate between normal and diseased cells in a variety of cell types and diseases, although mainly cancers (Paweletz *et al*., 2000a; von Eggeling *et al*., 2000; Batorfi *et al*., 2003; Zheng *et al*., 2003; Melle *et al*., 2003). The numbers of peaks generated in a sample vary with ProteinChip type, extraction buffer, and tissue and although reproducible protein "fingerprints" can be generated using as few as 25–100 cells, far more proteins can be seen with increasing loads and in most cases between 500 and 10 000 cells have been used, the amount of protein present in these dissections being very dependent on factors such as cell type and section thickness however. Although in a number of cases, particular discriminatory peaks have been found, the challenge now lies in being able to identify the particular proteins or protein fragments that will provide further information. One approach that was used successfully to identify a peak of approximately 36 kDa as annexin V, which discriminated between normal pharyngeal epithelium and head and neck squamous cell carcinoma was that of subsequent 2D-PAGE and MS sequencing (Melle *et al*., 2003). This was possible due to the size of this particular peak, making it amenable to such separation. However, for smaller proteins or fragments, this is still a challenge.

5. Summary

The number of studies using laser-based microdissection methods as a prelude to subsequent proteomic analyses is still small, but sufficient to illustrate the promise of such technology in overcoming the problems of tissue heterogeneity. The use of highly sensitive downstream analysis techniques that require relatively small amounts of sample, such as protein and antibody microarrays and MS profiling are likely to be the main areas in which such microdissection techniques will contribute more extensively in the future. The combination with multidimensional liquid chromatography tandem MS (*see* Article 13, **Multidimensional liquid chromatography tandem mass spectrometry for biological discovery**, Volume 5) is also a possibility, although not yet explored. The analysis of different cell populations in abnormal tissues will clarify the molecular basis of changes occurring in disease and during progression, and in defining the important role of interactions between the different cellular compartments. Ultimately, in addition to increasing our understanding of the underlying disease pathogenesis, this has the potential to contribute in various areas of clinical utility ranging from marker

discovery for diagnosis and prognosis, to identification of specific disease-related alterations in individuals and appropriate tailoring of targeted therapy.

Specialist Review

Orbitrap mass analyzer

Alexander Makarov
Thermo Electron, Bremen, Germany

Michaela Scigelova
Thermo Electron, Hemel Hempstead, UK

1. Introduction

The orbitrap mass analyzer is rightfully considered to be one of the newest analyzers. Its roots, however, can be traced back to 1923, when the principle of orbital trapping was proposed by Kingdon (1923). Experiments over the next half a century have shown that charged particles could be indeed trapped in electrostatic fields but they offered no hint of how this could be used for mass analysis. Simultaneously, advances in charged particle optics led to the development of a multitude of electrostatic fields (Korsunskii and Basakutsa, 1958). It was a quadro-logarithmic field used for orbital trapping of laser-produced ions that enabled Knight to perform crude mass analysis by applying axial resonant excitation to trapped ions (Knight, 1981). At the same time, this attempt demonstrated that the quest for a new mass analyzer would require a great deal of improvement in all key areas, most notably a more accurate definition of the quadro-logarithmic field, an ability to inject ions from an external ion source, and an improvement in ion detection.

These issues have been successfully addressed in the seminal work of Makarov (1999, 2000). A number of very significant technological advances were implemented, thus making the orbitrap analyzer usable in practical settings, namely, the development of pulsed injection from an external ion storage device (Hardman and Makarov, 2003; Hu *et al*., 2005; Makarov *et al*., 2006). Unique to the history of mass spectrometry, both proof of principle and product development have been carried out entirely within industry: from the first public announcement in 1999 till the entry into mainstream mass spectrometry in 2005.

The term *orbitrap* was first coined to define a mass analyzer wherein ions combine rotation around an electrode system with harmonic oscillations along the axis of rotation at a frequency characteristic of their *m/q* value (Makarov, 2000). The image current from coherently oscillating ions is detected on receiver plates as a time-domain signal. Fourier transform of this signal then gives us a mass spectrum. Therefore, the orbitrap analyzer extends the family of Fourier transform mass analyzers, which, until recently, contained only one widely used analyzer: Fourier transform ion cyclotron resonance (FTICR).

From the point of view of an ion optics design, the orbitrap analyzer belongs in the class of closed electrostatic traps. In theory, the ions could remain confined within such traps for an indefinite period of time. Other examples of closed electrostatic traps include ion storage rings, linear electrostatic rings, multiple-reflection ion mirrors, and so on. The harmonic nature of oscillations enables the orbitrap mass analyzer to provide the highest frequency and the highest quality of focusing in this group. This, in turn, gives the orbitrap analyzer its superior performance with respect to the dynamic range, mass accuracy, and resolving power that it is capable of achieving.

2. Fundamental principles of operation

2.1. Geometry of the analyzer

The geometry of the orbitrap mass analyzer is shown in Figure 1. The trap consists of an outer barrel-like electrode and a central spindlelike electrode along the axis. These electrodes are shaped in such a manner so as to produce the quadro-logarithmic potential distribution:

$$U(r, z) = \frac{k}{2}\left(z^2 - \frac{r^2}{2}\right) + \frac{k}{2} \cdot (R_m)^2 \cdot \ln\left[\frac{r}{R_m}\right] + C \quad (1)$$

where r, z are cylindrical coordinates ($z = 0$ being the plane of the symmetry of the field), C is a constant, k is field curvature, R_m is the characteristic radius. In this trap, stable trajectories combine rotation around the central electrode with oscillations along the axis, resulting in an intricate spiral (Makarov, 2000).

2.2. Motion of trapped ions

There are three characteristic frequencies of ion motion:

- frequency of rotation around the central electrode
- frequency of radial oscillations (between maximum and minimum radii)
- frequency of axial oscillations (along z-axis).

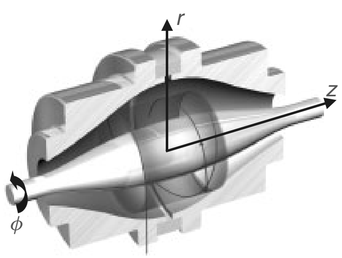

Figure 1 Diagram of the orbitrap mass analyzer showing a spiral trajectory of an ion

Only the last one is completely independent of initial velocities and coordinates of the ions. Therefore, only this frequency could be used for determinations of mass-to-charge ratios *m/q*:

$$\omega = \sqrt{\frac{q}{m} \cdot k} \tag{2}$$

wherein constant k comes from equation (1) and changes in proportion to the voltage between the central and the outer electrodes.

2.3. Ion detection

Axial oscillation frequencies can be directly detected by measuring the image current on the outer orbitrap electrodes as shown in Figure 1. A broadband detection is followed by a fast Fourier transformation (FFT) to convert the recorded time-domain signal into a mass-to-charge spectrum (Marshall and Verdun, 1990). The image current is amplified and processed exactly in the same way as for FTICR, resulting in a similar sensitivity and signal-to-noise ratios. However, there is a minor but important distinction: the square-root dependence originating from the electrostatic nature of the field causes a much slower drop in resolving power observed for ions of increased *m/q*. As a result, the orbitrap analyzer may outperform FTICR in this respect for masses above a particular *m/q* (typically, above 1–2000 *m/z*).

There could be an alternative way of detecting ions that follows the original proposal of Knight (1981): to excite ions axially using a voltage at a resonant frequency and to scan the mass range by sweeping this frequency. However, this approach would offer no advantage over conventional traps while at the same time lacking the ability to carry out MS^n experiments. Therefore, detection of the image current remains the major mode of operation for the orbitrap mass spectrometers.

2.4. Formation of coherent ion packets

The most important prerequisite for detection of the image current is the ability to concentrate all ions of the same *m/q*. The relevant dimensions of the ion cloud must be smaller than the amplitude of oscillations we wish to detect. This could be achieved in one of two ways:

- Broadband excitation of ions from the equatorial plane. Traditionally, this approach is used in FTICR and is compatible with well-known types of external ratio frequency (RF) storage devices. But such an approach demands substantial complexity of an ion introduction apparatus (Makarov, 1999).
- Excitation by off-axis injection of pulsed ion packets ("excitation by injection"). This approach minimizes perturbations of the quadro-logarithmic field but requires a very fast ejection of large ion population from an ion source or an external RF storage device.

Ultimately, the second approach has proved to be more practical and robust. It is performed according to the following sequence:

1. Ions are trapped in a gas-filled RF-only set of rods, preferably a linear ion trap. In principle, this also allows various manipulations of the ions, including isolation, fragmentation, MS^n, and so on.
2. Pulsed voltages are applied to the end electrodes (Hardman and Makarov, 2003; Hu *et al*., 2005) or across the RF electrodes (Makarov *et al*., 2006) so that the ions find themselves in a strong extraction field. The probability of collisions and collision-induced dissociation during the ion extraction is minimized by storing ions near the exit orifice. Additional lenses are used for the final spatial focusing of the ion beam into the entrance of the orbitrap analyzer, as well as to facilitate differential pumping to achieve the very high vacuum necessary for effective mass measurement.
3. Ions of individual mass-to-charge ratios arrive at the entrance of the orbitrap analyzer as a tight packet with dimensions considerably smaller than the amplitude of their axial oscillations. When ion packets are injected into the orbitrap analyzer off-axis (Figure 1), they start coherent axial oscillations without the need for any additional excitation.
4. Upon entering the orbitrap analyzer, the ion packets are "squeezed" by increasing the electric field to move the ions toward the equator and the central electrode. This increase in electric field is created by ramping up the voltage on the central electrode.
5. Because of the strong dependence of rotational frequencies on ion energies, angles, and initial positions, each ion packet soon spreads over the angular coordinate, forming a thin rotating ring. This has important ramifications: more ions can be present in the orbitrap mass analyzer before the space charge effects start impacting the mass resolution and accuracy of the measurement.

Following the injection, the voltages on both the central electrode and deflector are stabilized so that no mass drift can take place during the next stage (ion detection).

2.5. *Decay of coherent ion packets*

As mentioned earlier, under ideal conditions, the ions could remain in an electrostatic analyzer indefinitely. Unfortunately, the collisions with residual gas in the orbitrap cause ions to scatter and limit the time a transient can be detected for a period of a few seconds. A decay of the transient in the orbitrap mass analyzer and consequent limitation of resolving power is further caused by a loss of coherence due to miniscule imperfections of the orbitrap electrode manufacturing, and due to space charge repulsion. The transient could be further extended by improving the accuracy of electrodes and the vacuum.

The space charge repulsion is greatly reduced because of the shielding action of the central electrode that screens ions on one side of the ion ring from influencing ions on the other side. However, a due diligence in the design of the orbitrap

electrodes is needed to avoid more complex nonlinear effects caused by the interaction between nonlinear field perturbations and space charge.

2.6. Main analytical parameters of the orbitrap mass analyzer

Similar to other mass analyzers (e.g., a quadrupole), analytical parameters are determined to a large extent by the present status of manufacturing technology and electronics. The current level of machining precision enables the resolving power of the orbitrap mass analyzer to reach a value of several hundred thousands. Internal and thermal noise of electronic components impacts the sensitivity of detection of the image current in the orbitrap, making a couple of dozen ions its limit of detection. The mass error using external mass calibration is a few parts per million and remains stable over a 24-hour period. The accuracy is limited principally by the noise of electronic components. The repetition rate of a few hertz reflects the present speed at which we are able to apply a high voltage to the central electrode. While this combination of analytical parameters remains inferior to that of FTICR mass analyzers, it appears to be attractive enough given the absence of a superconducting magnet and of lower m/q ion losses suffered during transfer from an external ion storage device.

In comparison with other accurate-mass analyzers (e.g., time-of-flight analyzers), the orbitrap system offers much higher dynamic range over which accurate masses can be determined (extent of mass accuracy).

2.7. Fragmentation in the orbitrap mass analyzer

The ions trapped in the orbitrap analyzer have energies in the range of kiloelectron volts. A high-energy fragmentation caused by collision with residual gas happens automatically, and its extent could be regulated by gas pressure. Pulsed lasers could be another way to induce fragmentation of ions in the orbitrap. Unfortunately, when an ion decays under the dynamic trapping, its fragments will have the same velocity. As their energy is proportional to their individual mass-to-charge ratios, the trajectories become highly elliptical. Therefore, low-mass fragments (with m/q typically below 30–50% of that of the precursor ion) will fall onto the central electrode, while lower-charge state fragments (with m/q typically above 50% of the precursor ion) will hit the outer electrodes. This property seriously limits the utility of the analyzer for MS^n, especially taking into consideration the absence of collisional cooling, increased cycle time, inferior resolving power and sensitivity, cost, and complexity of such an apparatus.

2.8. The orbitrap analyzer used as an accurate-mass detector in hybrid mass spectrometers

The challenging nature of the technical issues related to performing MS/MS in the orbitrap mass analyzer was the main reason behind the concept of using it as an

accurate-mass detector for another mass analyzer: linking two mass spectrometers into one hybrid instrument. If we also insert an ion storage device between the first mass analyzer and the orbitrap, the analyzers are effectively decoupled from each other and any mass analyzer could be used as the first stage.

In the first commercial orbitrap-based instrument, a linear ion trap with radial ejection (Schwartz 2005) was chosen as a "partner" for the orbitrap mass analyzer because of its very high sensitivity, superb control of the ion population, short cycle time, and MS^n capability. Depending on the requirements for the analysis, the two analyzers can be used independently or in concert. It is worth pointing out that the MS/MS spectra generated in the linear ion trap and the orbitrap mass analyzer are very similar, with the only major difference being the resolution and mass accuracy of the observed peaks.

The ion storage device linking the linear ion trap to the orbitrap analyzer is called the *C-trap*. The C-trap has a high space charge capacity (Makarov *et al*., 2006), and enables several intriguing modes of operation:

- Ions can be fragmented by injecting them into the C-trap at higher energies to yield fragmentation patterns similar to those in triple-quadrupole mass spectrometers.
- The C-trap supports multiple fills. An injection of a fixed number of ions of a known compound can be followed by injection of analyte ions. Both sets of ions are then injected simultaneously into the orbitrap. This allows for a robust internal calibration of each spectrum.
- Multiple injections of ions fragmented or selected at different conditions could be stored together and acquired in a single orbitrap spectrum.
- Additional fragmentation methods could be used within the ion storage device, for example, IRMPD (infrared multiphoton dissociation), ion-molecule reactions, and ETD (electron transfer dissociation).

The next section describes selected analytical applications of the hybrid LTQ orbitrap mass spectrometer.

3. Analytical applications of the orbitrap mass analyzer

The key attributes of the orbitrap analyzer, namely, ruggedness, high mass accuracy, and excellent resolving power, make it suitable for both proteomics and small-molecule analyses. Details regarding recently published proteomics applications can be found in Scigelova and Makarov (2006), and a short overview is presented here.

The main benefit to the user is that a very accurately measured mass of a peptide allows for a considerable reduction of false positive identifications, thus resulting in a *highly confident identification*. The high resolving power helps deal effectively with extremely complex peptide mixtures. Figure 2 illustrates this point; the mass of the two coeluting isobaric peptides can be accurately determined only if peaks are sufficiently resolved.

On the other hand, the fragmentation (MS/MS) spectra of peptides for database searches might not be necessarily required with such high precision. When MS/MS

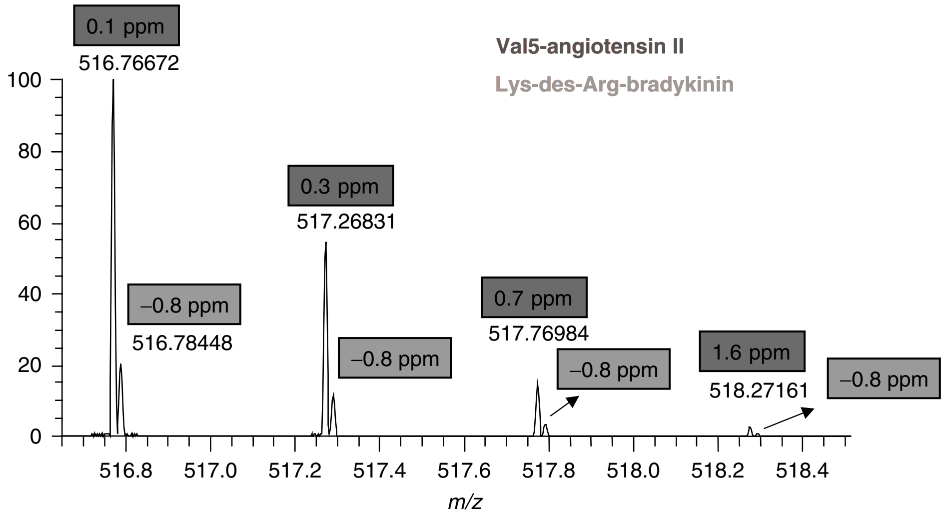

Figure 2 Analyzing isobaric peptides. The two peptides need to be sufficiently resolved (resolving power 60 000 was used in the experiment) to allow for an accurate-mass assignment

spectra is recorded with the linear ion trap detector, three spectra per second can be comfortably obtained. Both mass analyzers can indeed work in parallel: while a high-resolution/mass accuracy spectrum of the precursor is being acquired in the orbitrap, the fast linear ion trap carries out fragmentation and detection of MS/MS (or higher-order MS^n) spectra of selected peptides. A true parallel operation is achieved by allowing for a short preview of ions that are being measured in the orbitrap analyzer. This preview defines the parent ions that the linear ion trap will fragment. Within one second, one orbitrap spectrum acquired at resolving power 60 000 together with three linear ion trap fragmentation spectra can be obtained (Makarov *et al*., 2006).

Analysis of *posttranslational modifications* is an area of proteomics that greatly benefits from accurate-mass measurement as well as multiple levels of fragmentation (Olsen *et al*., 2006). An accurate measurement of the neutral loss of phosphate from the precursor ion in the MS/MS spectrum allows for a selective targeting of phosphopeptides in complex mixtures, while the site of phosphorylation is confidently identified in the following MS^3 spectrum.

De novo sequencing of peptides is arguably the biggest challenge in proteomics. The problem is compounded by a “combinatorial explosion” caused when considering multiple modifications. Mass accuracy and high resolution considerably improve the results of de novo interpretation of peptide MS/MS spectra using computer algorithms (Figure 3).

The orbitrap mass analyzer offers sufficiently high resolving power to encourage attempts at analyzing medium-sized proteins (10–25 kDa, Figure 4). This approach, called a *top-down analysis*, enables a detailed characterization of the protein, including the determination of posttranslational modifications.

In the areas related to small molecule analysis, the ability to conduct *biotransformation profiling* via tandem mass spectrometry coupled with accurate-mass

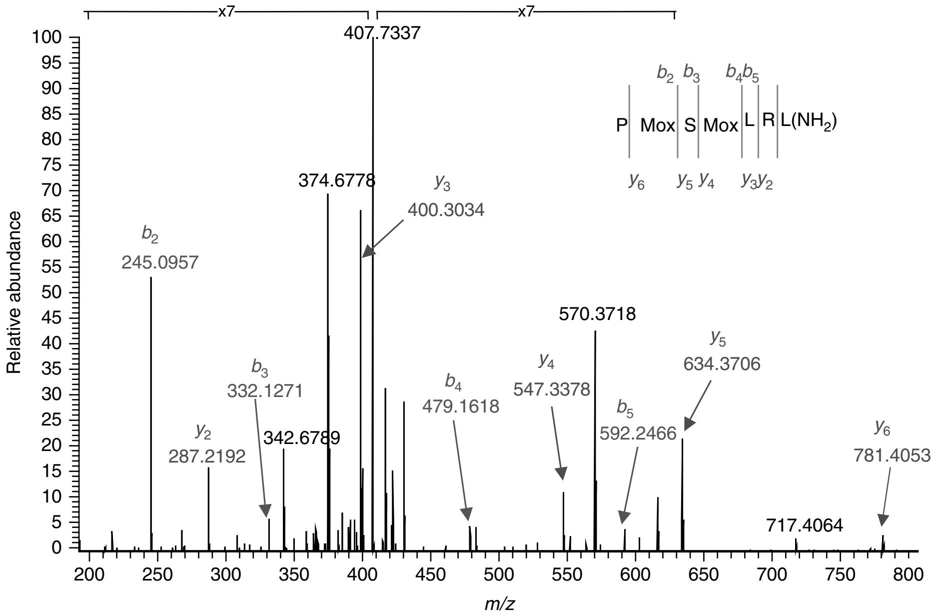

Figure 3 De novo sequence assignment of a snail peptide. Note the presence of three modified amino acid residues. It is worth pointing out that the orbitrap mass analyzer confidently differentiates between oxidized methionine and phenylalanine candidates (mass difference 0.033 u). (The sample was kindly provided by Dr Ka Wan Li of the Free University, Amsterdam. measurement, all in a single experiment, is clearly one of the most attractive features of the orbitrap mass analyzer. The tight mass tolerance reduces or eliminates background chemical noise. Thus, suspected metabolites can be confirmed or refuted using (1) the predictive chemical formula and corresponding mass error of the analysis, (2) ring-plus double bond equivalent rule, and (3) accurate-mass measurement of product ion spectra of suspected metabolites (Peterman *et al*., 2006).

In the context of whole biological systems, the study of *metabolic networks* has so far been hindered by the lack of techniques that identify metabolites and their biochemical relationship. The orbitrap mass analyzer is proving to be very useful in this field (Breitling *et al*., 2006).

In some areas of research, the use of a high-resolution/accurate-mass analyzer with MS^n capabilities is poised to cause a major shift in experimental approaches and strategies. For instance, the study of lipid mixtures traditionally using parent and neutral ion scanning on triple-quadrupole mass spectrometers is now able to adopt a “profiling” approach relying on high resolution/accurate mass (Ejsing *et al*., 2006). This approach has the potential to revolutionize the *study of lipids*, making it a high-throughput global approach akin to biomarker discovery in the areas of proteomics and metabolomics.

Yet another interesting application of the orbitrap mass spectrometer to small molecule analysis is in the area of *drugs of abuse*. The orbitrap analyzer allows for a

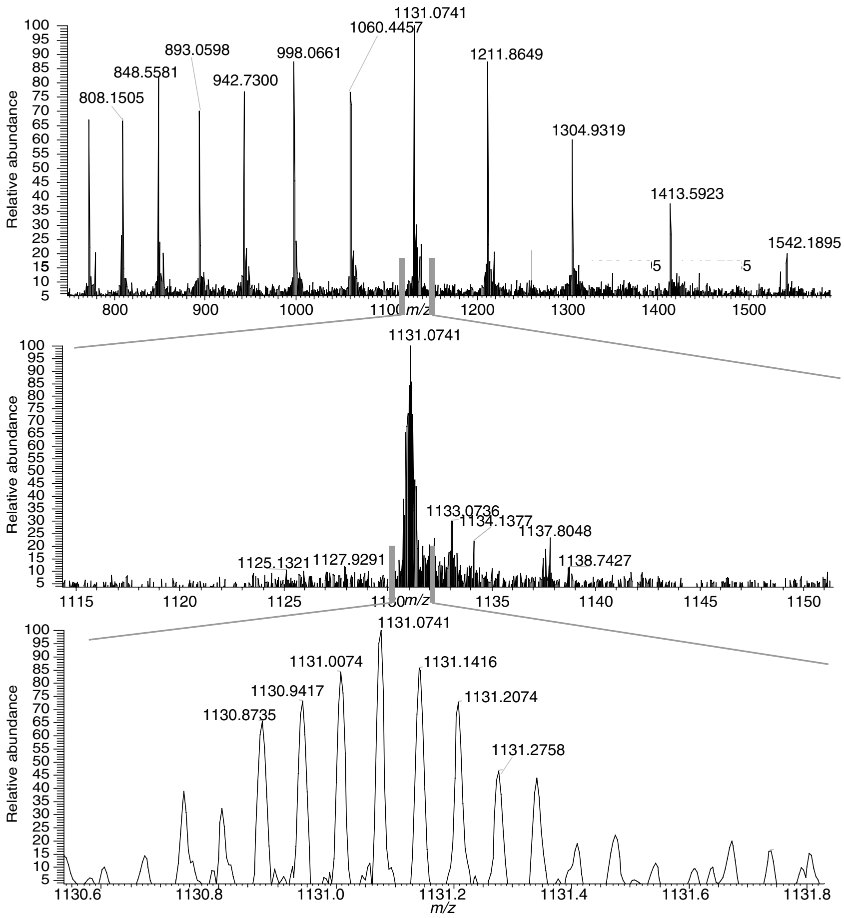

Figure 4 Intact myoglobin is measured in the orbitrap mass analyzer at resolving power 100 000 in an infusion experiment. (Reprinted from Scigelova M and Makarov A (2006) Orbitrap mass analyzer – overview and applications in proteomics. *Practical Proteomics*, **1**, In press, with the permission of the copy-right owner)

thorough characterization of novel compounds that have a high potential for misuse in sports (Thevis *et al*., 2006a, 2006b). The MS^n capability of the hybrid linear ion trap–orbitrap mass spectrometer is used to determine fragmentation pathways while a routine analysis is then conducted on a triple-quadrupole mass spectrometer.

In conclusion, it is clear that the orbitrap mass analyzer is fast becoming a unique and powerful addition to the scientific toolbox for probing biological systems and increasing selectivity and confidence of routine analyses. The above shortlist of applications is bound to expand considerably in the near future as the orbitrap systems are becoming more widespread and penetrate into other areas of research. Undoubtedly, we will see major breakthroughs in the design and development of the orbitrap analyzer technology.

Short Specialist Review

Time-of-flight mass spectrometry

Robert J. Cotter
Johns Hopkins University School of Medicine, Baltimore, MD, USA

1. Introduction

Time-of-flight (TOF) mass spectrometers were introduced in the 1940s (Stephens, 1946; Cameron and Eggers, 1948) and commercialized in 1955 (Wiley and McLaren, 1955). Regarded for many years as instruments with low mass range and low resolving power, TOF mass spectrometers were "rediscovered" following the introduction of ionization techniques capable of ionizing biological macromolecules including proteins and peptides, oligosaccharides, glycolipids and other glycoconjugates, and polynucleotides. Thus, they have become important for proteomics not only in their ability to obtain molecular weights of intact proteins but also for obtaining amino acid sequences of peptides and for locating and characterizing posttranslational modifications.

2. Mass analysis and mass range

The basic TOF mass spectrometer consists of a small source region s, a longer drift length D and a detector (Figure 1a). Ions are formed in the source by any number of ionization techniques that have included *electron ionization* (EI) (Wiley and McLaren, 1955), *chemical ionization* (CI) (Futrell *et al*., 1968), *plasma desorption mass spectrometer* (PDMS) (Torgerson *et al*., 1974), *laser desorption* (LD) (Van Breemen *et al*., 1983), *matrix-assisted laser desorption/ionization* (MALDI) (Karas and Hillenkamp, 1988; Tanaka *et al*., 1988), and *electrospray ionization* (ESI) (Verentchikov *et al*., 1994). Ions of all masses m are then accelerated as they exit the source to final kinetic energies $\frac{1}{2}mv^2 = eV$, where e is the charge on an electron and V is the voltage across the source. The ions then travel through a drift length at velocities v, which are constant but different for each mass, before striking the detector. The TOF for an ion is then given by

$$t = \left(\frac{m}{2eV}\right)^{1/2} (2s + D) \approx \left(\frac{m}{2eV}\right)^{1/2} D \qquad (1)$$

In theory, the mass range of such an instrument is unlimited. For current instruments using MALDI, detectors limit the mass range, as the efficiency for conversion

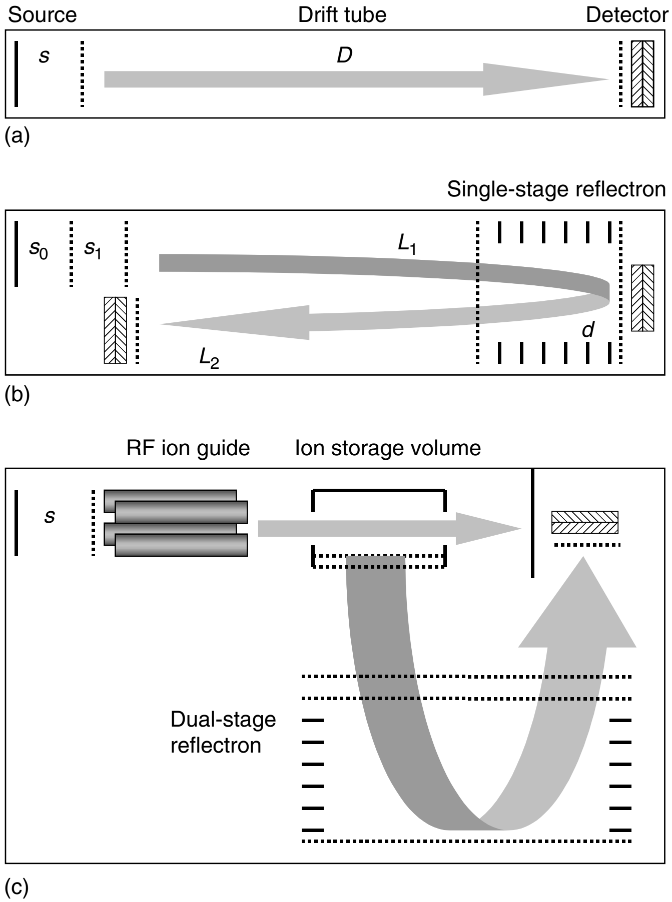

Figure 1 Basic configurations of time-of-flight mass spectrometers: (a) a simple linear TOF mass analyzer with a single-stage ionization source, (b) a *reflectron* TOF mass analyzer with a dual-stage ion extraction source, and (c) an *orthogonal acceleration* mass analyzer with a *quadrupole ion guide* and a dual-stage reflectron

of incoming ions to an electron cascade by electron multipliers and channel plate detectors depends upon ion velocity. That velocity is slower for higher mass ions and is the reason that current instruments operate at high (generally 20 kV) accelerating voltages. At the same time, cryo-cooled superconducting tunneling junction (SJT) (Hilton *et al*., 1998) detectors are now providing megadalton detection, but at lower time resolution.

3. Spatial, energy distributions and mass resolution

The expression for mass resolving power: $m/\Delta m = t/2\Delta t$ indicates that this will be only as good as our ability to parse the time measurement into very small time intervals. The *boxcar* method used by early commercial instruments (which

enabled recording of only one time interval in each TOF cycle) (Holland *et al.*, 1983) was capable of resolving time intervals ranging from 10 to 40 ns. Today, fast analog-to-digital converters (transient recorders, waveform recorders, and digital oscilloscopes) have digitization rates up to 8 Gsample s^{-1}, corresponding to time intervals of 125 ps. When single ion counting is used, time-to-digital converters (TDCs) provide an accuracy of 200–500 ps.

Mass resolution is also affected by the initial conditions of ions. For example, ions formed at different distances between the back of the source and the extraction grid will have different kinetic energies as they leave the source, and therefore different velocities and different TOFs. This is because an initial *spatial distribution* is effectively a different distance s, and a different energy due to acceleration $eV = eEs$, where E is the electric field in the source. Ions may, of course, have different kinetic energies before or as a result of ionization. This initial *kinetic energy distribution* U_0 means that ions will have different final energies as well: $eV + U_0$. The effects of both of these are given in a more complex TOF equation:

$$t = \frac{(2m)^{1/2}}{eE}\left[(U_0 + eEs)^{1/2} \mp U_0^{1/2}\right] + \frac{(2m)^{1/2} D}{2\,(U_0 + eEs)^{1/2}} \tag{2}$$

The first term is the time in the source and includes the so-called turn-around time (Wiley and McLaren, 1955), since the initial velocity component along the flight path may be in the forward or reverse direction. The second term is the time in the flight tube and reflects the final energy. While the turn-around time is important in gas phase ionization methods, such as EI, it is generally not in methods such as MALDI in which ions are formed on a surface.

The effects of the initial spatial distribution are the easier of the two to correct. Ions formed about a small distance $s + \Delta s$ will be focused to first order at a distance $d = 2s$ from the source, the so-called *space-focus plane*. Because this distance is not far enough from the source to enable sufficient mass/time dispersion and achieve good resolving power, it is more common to use a *dual-stage extraction* source (Figure 1b), in which the field strength E_1 in the second region s_1 is much greater than that E_0 in the first s_0. In this case, the space focus is given by

$$d = 2\sigma^{1/2}\left[\frac{1}{s_0^{1/2}} - \frac{2s_1}{s_0^{1/2}\left(\sigma^{1/2} + s_0^{1/2}\right)^2}\right] \tag{3}$$

where $\sigma = s_0 + (E_1 E_0)s_1$. In addition, it is possible to achieve better (second order) focusing for an optimal set of parameters.

4. Time-lag focusing and delayed extraction

The greatest challenge for achieving high resolving power is the simultaneous focusing of the initial spatial and energy distributions. The *time-lag focusing* method of Wiley and McLaren introduced a delay time between the ionizing

electron beam pulse forming the ions and the extraction pulse accelerating them from the source. During that time, ions with larger forward velocity would move closer to the extraction grid, so that they would receive less energy from acceleration than slower moving ions. Prior to the development of MALDI this approach was used for infrared laser desorption (IRLD) (Van Breemen *et al.*, 1983; Tabet and Cotter, 1984).

Laser microprobes (Hillenkamp *et al.*, 1975) and PDMSs (Torgerson *et al.*, 1974) relied on the fact that ions formed directly from a surface would have a very minimal spatial distribution, so that correction of the kinetic energy could be accomplished, without pulsed extraction, using a reflectron (see below). Following the introduction of MALDI[7] (Karas and Hillenkamp, 1988; Tanaka *et al.*, 1988) there was a return of interest in pulsed extraction methods (Whittal and Li, 1995; Brown and Lennon, 1995; Vestal *et al.*, 1995), which have produced very high mass resolutions. While known commonly as *delayed extraction*, King *et al.* (1995) have termed this approach *velocity-space correlated focusing* because the spatial distribution at the time of the extraction pulse (which is absent initially) is derived entirely from the initial velocities (energies).

Time-lag focusing and the more recent pulsed extraction methods are generally accomplished with dual-stage extraction and are all mass dependent. Because the velocity distributions will be different for different masses, motion during the delay period will be different. Thus, either the delay time or the ratio E_1/E_0 is different for each mass. Over many years a number of dynamic methods have been developed, including *impulse field focusing* (Marable and Sanzone, 1974), *postsource pulsed focusing* (Kinsel and Johnston, 1989), *velocity compaction* (Muga, 1988), and *dynamic-field focusing* (Yefchak *et al.*, 1989). *Mass-correlated acceleration*, developed more recently (Kovtoun *et al.*, 2002), takes advantage of the fact that heavier ions enter the second region later than lighter ions and dynamically changes the field E_1 by raising the flight tube voltage. In many cases, it is found that focusing in the middle mass range (5000–6000 Da) produces reasonable focus throughout the useful mass range for MALDI.

5. Reflectrons and postsource decay

Mamyrin and coworkers first reported their *reflectron* or *ion mirror* in 1973 (Mamyrin *et al.*, 1973). Shown in Figure 1b, this mass analyzer incorporates a retarding electric field that reverses the direction of the ions. The device works to correct for an initial kinetic energy spread because the higher velocity ions penetrate more deeply into the reflectron and take longer to turn around. For a single-stage reflectron:

$$t = \left(\frac{m}{2eV}\right)^{1/2} [L_1 + L_2 + 4d] \tag{4}$$

where L_1 and L_2 are the drift paths toward and away from the reflectron, and d is the penetration depth. The single-stage reflectron (Tang *et al.*, 1988) provides first order energy focusing, while the dual-stage reflectron (an example is shown

in Figure 1c) can provide second order focusing. A *quadratic reflectron* (Mamyrin, 1994) provides (in theory) infinite order focusing, that is, the flight time is independent of energy, but the nonlinear field along the center axis also includes off-axis field lines that cause divergence of the ion beam and loss of transmission.

When an ion of mass m_1 originating from the source dissociates to form a fragment m_2 in the flight tube, its flight time through a single-stage reflectron is

$$t = \left(\frac{m_1}{2eV}\right)^{1/2}\left[L_1 + L_2 + 4\frac{m_2}{m_1}d\right] \quad (5)$$

This offers the opportunity to select a given precursor ion m_1 using an electronic gate in the flight tube L_1 and to record the flight times of all the product ions m_2, a method generally referred to as *postsource decay* (PSD) (Kaufmann *et al*., 1994). Focusing is poorer for lower mass product ions that do not approach the optimal penetration depth, a problem that is generally addressed by acquiring multiple spectral segments at reduced reflectron voltage. The *curved-field reflectron* (CFR) (Cornish and Cotter, 1993; Cornish and Cotter, 1994) eliminates the need for stepping the reflectron voltage, focusing the entire product ion mass range simultaneously. Though this reflectron uses a nonlinear field, it is closer to the constant field reflectron than to the quadratic, so that high ion transmission is maintained.

6. Orthogonal acceleration

The development of *orthogonal acceleration* (oaTOF) mass spectrometers has not only provided a means for achieving high mass resolution but has also provided the opportunity to utilize continuous ionization sources, most notably electrospray ionization. The first such instrument by Dawson and Guilhaus (1989) used an EI source and extraction into a linear TOF mass analyzer, while a later instrument by Mirgorodskaya *et al*. (1994) used an ESI source with a reflectron. Essential to the operation of the instrument (and to its ultimate mass resolution) is the collimation of the ion beam into a storage volume (Figure 1c) so that the remaining component of the velocity spread is directed along a single axis. Ions are then extracted orthogonal to that axis, using space focusing to correct for any width in the collimated beam. While a collimated beam can be achieved by passing the beam through a small orifice, much better transmission can be achieved using a quadrupole, hexapole, or octapole ion guide (Krutchinsky *et al*., 1998). With such a configuration, the mass analyzer is effectively isolated from the source and has no memory of the initial conditions of the ions. Thus, multiple sources can be used, as can atmospheric pressure sources such as electrospray and atmospheric pressure MALDI (AP MALDI) (Laiko *et al*., 2000).

7. Hybrid instruments

The development of oaTOF mass spectrometers has provided the opportunity for a very successful tandem (hybrid) configuration that combines a quadrupole mass

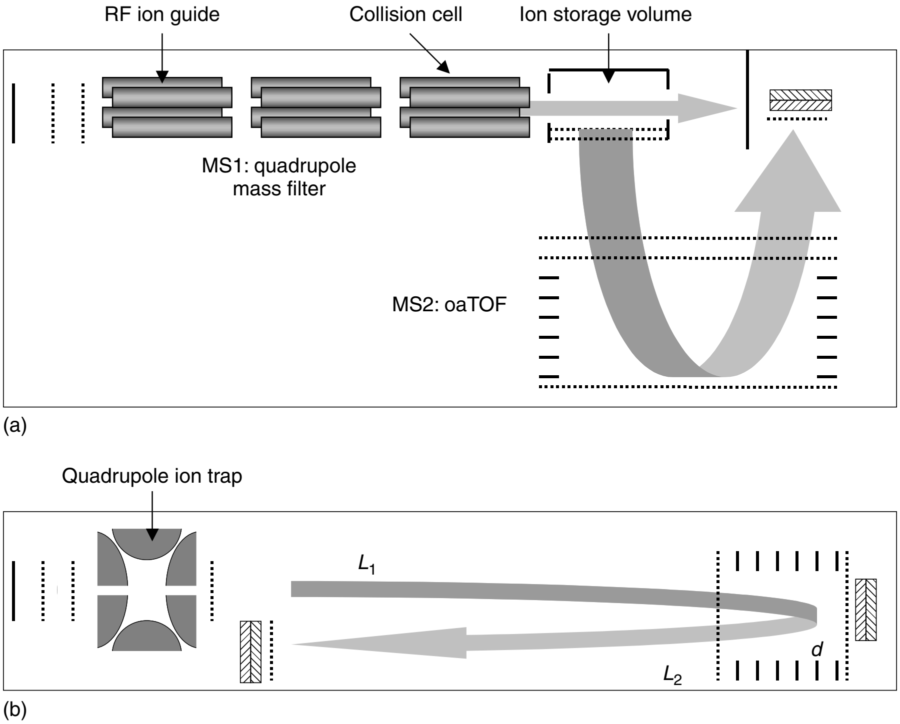

Figure 2 Hybrid instruments: (a) a tandem quadrupole/time-of-flight mass spectrometer with an RF ion guide and collision chamber, and (b) a tandem ion trap/time-of-flight mass spectrometer

analyzer in the first stage and an orthogonal TOF as the second mass analyzer (Figure 2a) (Shevchenko *et al*., 1997; *see also* Article 10, **Hybrid MS**, Volume 5). In a tandem experiment, the first mass analyzer is generally used to pass a precursor mass while the second mass analyzer scans its product ion spectrum; thus, the quadrupole is an appropriate mass filter as the first stage while the TOF analyzer provides the multichannel advantage for recording the product ion spectrum. The mass/charge range of quadrupoles is more limited than the TOF, but is nicely compatible with the multiply charged ions from an electrospray source, which it accommodates using an RF ion guide as described above. An additional quadrupole provides a low energy *collision-induced dissociation* (CID) chamber for inducing fragmentation. Because fragmentation of multiple-charged ions is generally accompanied by charge reduction, product ions may have considerably higher *m/z* than their precursors, but this is easily accommodated by the TOF analyzer. An additional advantage is that selection of the precursor ion mass is much better than it is on the TOF/TOF instruments described below.

A configuration utilizing an electrostatic ion trap (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5) with the TOF mass spectrometer was introduced by Chien and Lubman (1994), and was also intended to provide compatibility between a continuous beam ESI source and the pulsed TOF mass analyzer. A *trapTOF* instrument with a quadratic reflectron was reported by

Doroshenko and Cotter (1998). An advantage of the combined ion trap/TOF (Figure 2b) is that one can carry out MS^n analyses. While this is possible on an ion trap alone, the recorded spectrum at any stage of MS^n on the ion trap/TOF is always a TOF spectrum with higher mass resolution than can be obtained on the trap.

8. Tandem time-of-flight mass spectrometers

The difficulties inherent in stepping the reflectron voltage for PSD, as well as an interest in providing collision-induced dissociation of larger singly charged ions, has motivated the development of tandem TOF (or TOF/TOF) mass spectrometers. Such instruments are not entirely new; a very simple linear system designed by Jardine *et al*. (1992) used a voltage step after the collision cell to differentiate the flight times of the product ions. Beussman *et al*. (1995) and Cotter and Cornish (1993) both reported instruments using two reflectrons in a *Z* geometry in 1993. In the first instrument, photodissociation of the precursor ion was followed by additional acceleration of the product ions to accommodate the bandwidth of the reflectron; in the latter, pulsed CID was followed by a CFR to enable focusing of the product ions.

The most recent approaches to TOF/TOF design use a linear, pulsed extraction first analyzer, a mass selection gate at (or near) the space-velocity focus point, a collision chamber, and a second reflectron mass analyzer (Figure 3). These instruments differ in how they address the focusing of product ions in the reflectron. Specifically, precursor ions of mass m_1 produce product ions m_2 whose kinetic energies are proportional to their masses: (m_2/m_1) eV. Thus, product ion energies can range from the precursor ion energy (typically 20 keV) to a few eV, while single and dual-stage reflectrons focus only a fraction of that energy range. In one configuration (Figure 3a), precursor ions are decelerated to 2 keV prior to collision. After the collision, the product ions are pulse extracted from (effectively) a second source, which reaccelerates the ions by an additional 18 keV, so that ions with an energy range from 18 to 20 keV enter the reflectron (Medzihradszky *et al*., 2000). In a second approach (Figure 3b), precursor ions leave the source and enter the collision chamber at 8 keV and are not decelerated. The product ions (still traveling at the same velocity) enter a field-free *lift cell* whose potential is raised (by 19 kV) while the ions are in residence (Suckau *et al*., 2003). A third configuration (Figure 3c) uses a CFR to focus all the product ions resulting from 20-keV collisions, obviating the need for decelerating, reextracting, or lifting the product ions (Iltchenko *et al*., 2004). These configurations provide much-improved approaches compared with stepping of the reflectron voltage, plus the opportunity to locate mass selection at the space-velocity focus point and to carry out CID between the mass analyzers. Interestingly, MS/MS spectra on these instruments are not very different with and without a collision gas, which suggests that the processes are fundamentally the same: PSD or *laser induced dissociation* producing high internal energies, with fragmentation then aided by the collisions. At the same time, one observes the appearance of (or increases in) internal and single amino acid ions, which may result from a second, collision-induced fragmentation (Medzihradszky *et al*., 2000; Iltchenko *et al*., 2004; *see also* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5).

9. Future prospects

There is considerable interest in the development of compact, field-portable and/or miniaturized mass spectrometers; in this area, the TOF offers the possibility for retaining the same high mass range as its larger, high-performance counterparts (English *et al*., 2003). While such instruments are expected to play a significant future role in proteomics-based, point-of-care diagnostics, it is also clear that there is currently an increasing demand for high-performance instrument for the identification and validation of biomarkers. This includes both high mass resolution and MS/MS capabilities.

Short Specialist Review

Quadrupole mass analyzers: theoretical and practical considerations

Frank A. Kero and **Richard A. Yost**
University of Florida, Gainesville, FL, USA

Randall E. Pedder
Ardara Technologies LP, Monroeville, PA, USA

1. Introduction

Quadrupole mass analyzers are dynamic mass filters that play a central role in mass spectrometric proteomic investigations. Quadrupoles are used both alone and in tandem for the isolation (by mass-to-charge) of ions; they may also be used (in RF-only mode) to contain ions during collision-induced dissociation (CID) (Yost and Enke, 1979). Gas-phase ions are generated by a source external to the quadrupole mass analyzer, often at atmospheric pressure. It should be noted that ion production at one atmosphere is an important practical advantage, in that it allows for the easy exchange of ion sources without disturbing the vacuum of the quadrupole region (Cole, 1997). Peptides and proteins are typically introduced into the ion source in the liquid phase either from an HPLC column (for LC/MS), by flow injection analysis (with no HPLC column), or by continuous direct infusion through a fused silica capillary. For heterogeneous samples, a sample cleanup or separation technique such as HPLC or solid-phase extraction is typically incorporated into the method development scheme to allow for the sequential introduction of multiple analytes into the ion source. Simultaneous ionization of multiple analytes, particularly at widely varying concentrations, may result in suppression and prove deleterious in quantitative investigations (Cole, 1997; King *et al*., 2000; Constantopoulos *et al*., 1999).

The most common ionization source coupled with quadrupole mass analyzers for proteomics studies is electrospray ionization (ESI), since it is ideal for compounds such as peptides and proteins that can be ionized in solution. The fundamentals of ESI mechanisms have been described elsewhere (Cole, 1997; Kebarle, 2000; Cech and Enke, 2001). A key advantage of ESI is the ability to impose multiple

charges on an analyte upon ionization. Recall that ions are separated in mass analyzers as a function of their respective mass-to-charge ratios (*m/z*) (Throck Watson, 1997). It follows that multiple charging reduces the mass-to-charge ratio of ions, and thereby extends the mass range of the instrument. Atmospheric pressure chemical ionization (APCI) is a highly efficient alternative to ESI for less polar compounds. ESI and APCI are complementary techniques, as reflected in the phase in which charge transfer processes occur (King *et al*., 2000). Ionization for ESI occurs in the liquid phase, whereas ionization for APCI occurs in the gas phase. Both APCI and ESI are suitable ionization sources for a quadrupole mass analyzer because the ions are generated and transmitted as a continuous beam of ions. The other primary ionization method for proteomics studies is matrix-assisted laser desorption/ionization (MALDI). Since MALDI produces narrow pulses of ions, it is a far better marriage with pulsed mass analyzers (such as time-of-flight mass analyzers; *see* Article 11, **Nano-MALDI and Nano-ESI MS**, Volume 5 and Article 14, **Sample preparation for MALDI and electrospray**, Volume 5) than with the continuous mass analyzers such as quadrupoles. Furthermore, MALDI yields almost exclusively singly charged ions, and thus benefits from the essentially unlimited mass range of the time-of-flight mass analyzer. Quadrupole mass analyzers are also commonly used in mass spectrometers employing electron ionization (EI) and chemical ionization (CI), such as those coupled with gas chromatographs (GC/MS). These ionization techniques do not play a significant role in modern proteomic investigations, however.

The purpose of this communication is to provide the reader with a balanced treatment of practical and theoretical considerations for quadrupole mass analyzers, and to present the advantages of interfacing quadrupoles in tandem.

2. Theory and practice of quadrupole mass filters

A quadrupole mass analyzer consists of four electrically isolated hyperbolic or cylindrical rods linked to RF (radio frequency) and DC (direct current) voltages, as described by the schematic in Figure 1 (Pedder, 2001). The combination of RF and DC voltages creates a region of strong focusing and selectivity known as a hyperbolic field. In simplest terms, the ratio of RF/DC allows for the selective transmission of ions of a narrow range of mass-to-charge from the total population of ions introduced from the ionization source.

The idealized hyperbolic field can be described in terms of Cartesian coordinates (x and y directions toward the rods, and z direction along the rods' axis). Ions of a selected *m/z* follow a stable trajectory around the center of the field, and are transmitted in the z direction through the device (Dawson and Douglas, 1999). Motion of these "stable ions" in the x and y directions are small in amplitude, as the lowest energy pathway lies toward the center of the hyperbolic field. Ions of other *m/z* will have unstable trajectories, with increasing displacement in the x and y directions away from the center of the hyperbolic field, and thus strike the quadrupole rods, where they neutralize upon contact. These ions will not transmit efficiently through the quadrupole to the detector. The application of RF and DC voltages creates a region of stability for transmission of ions of a limited *m/z*

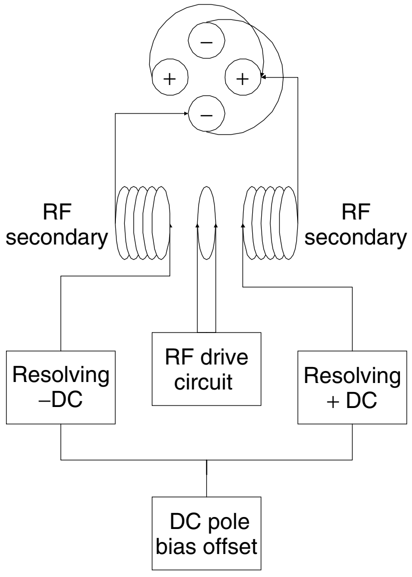

Figure 1 The quadrupole mass filter and its power supply

range. In this regard, the quadrupole analyzer is operating as a mass filter. A mass spectrum is produced by ramping the RF and DC voltages at a nearly constant ratio. Ions of increasing *m/z* will sequentially achieve stable trajectories and reach the detector in order of increasing *m/z*.

To understand the behavior of ions in the quadrupole, a brief introduction to the mathematics associated with ion motion is worthwhile. For a complete discussion, the reader is referred to the work of March and Hughes (1988).

The motion of ions through a quadrupole is described by a second-order linear differential equation called the Mathieu equation, which can be derived starting from the familiar equation relating force to mass and acceleration, $F = ma$, yielding the final parameterized form, with the following substitutions for the parameters a and q (Dawson, 1976):

$$\frac{d^2u}{d\xi^2} + (a_u - 2q_u \cos 2\xi)u = 0 \quad a_u = \frac{8eU}{m{r_0}^2\Omega^2} \quad q_u = \frac{4eV}{m{r_0}^2\Omega^2} \qquad (1)$$

The u in the above equations represents position along the coordinate axes (x or y), ξ is a parameter representing Ωt/2, t is time, e is the charge on an electron, U is the applied DC voltage, V is the applied zero-to-peak RF voltage, m is the mass of the ion, r_0 is the effective radius between electrodes, and Ω is the applied RF frequency in radians s^{-1}. The parameters a and q are proportional to the DC voltage U and the RF voltage V, respectively.

The analytical solution to this second-order linear differential equation is:

$$u(\xi) = \Gamma \sum_{n=-\infty}^{\infty} C_{2n} \exp(2n + \beta)i\xi + \Gamma' \sum_{n=-\infty}^{\infty} c_{2n} \exp -(2n + \beta)i\xi \qquad (2)$$

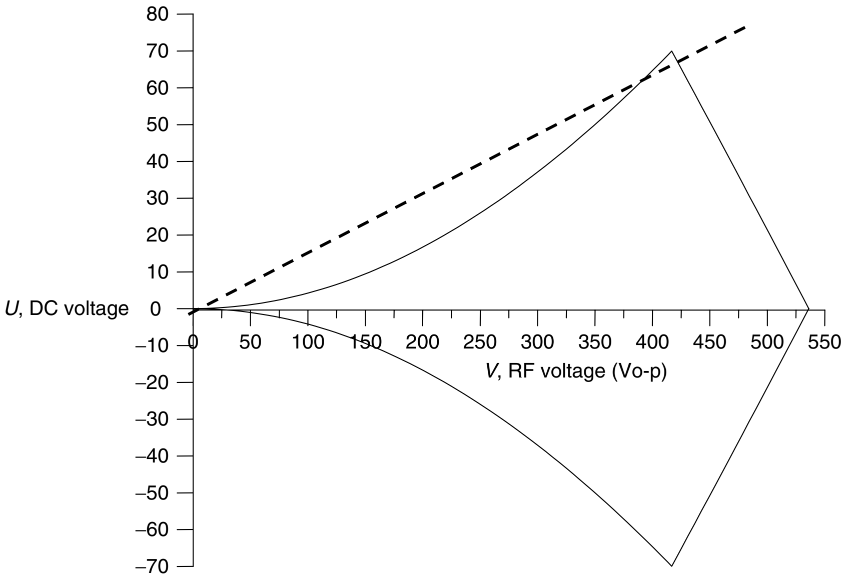

Figure 2 Mathieu stability diagram for an ion of *m/z* 219 in a quadrupole mass filter with 9.5-mm diameter round rods and an RF frequency of 1.2 MHz (Pedder, 2001)

which reduces to a similar infinite sum of sine and cosine functions:

$$u(\xi) = \sum_{n=-\infty}^{\infty} A_n \sin \omega_n + \sum_{n=-\infty}^{\infty} A_n \cos \omega_n \tag{3}$$

The solutions to the Mathieu equation can be presented graphically, as shown in Figure 2 in a so-called stability diagram. Points in (U, V) space (DC, RF voltage space) within the lines lead to stable trajectories for the *m/z* 219 ion; points outside the lines will lead to an unstable trajectory. The dotted line is called the scan line, and shows the ramp of RF and DC voltage at a nearly constant ratio (the slope of the line). If the line passes just under the apex of the stability region, as shown here, the *m/z* 219 ions will have a stable trajectory at those voltages, and will be transmitted to the detector.

Figure 3 shows the stability diagram for three different ions, of *m/z* 28, 69, and 219. Note that ions of lower *m/z* have stable trajectories at lower RF and DC voltages (i.e., they are stable at points in (U, V) space closer to the origin). The dotted scan line again shows the ramp of RF and DC voltage at a constant ratio (Pedder, 2001). The scan line passes through the apices of the stability regions for all three ions. As the RF and DC voltages ramp up in amplitude, ions of increasing *m/z* have stable trajectories and are transmitted, as shown in the dotted mass spectrum below the stability diagram. If the scan line has a lower slope (the solid line), it passes through a larger portion of each stability region, resulting in a mass spectrum with lower resolution, as shown as well.

The selection of RF and DC voltages, V and U, the RF frequency, Ω, and the inscribed radius r_0 between the rods determines the performance of the quadrupole

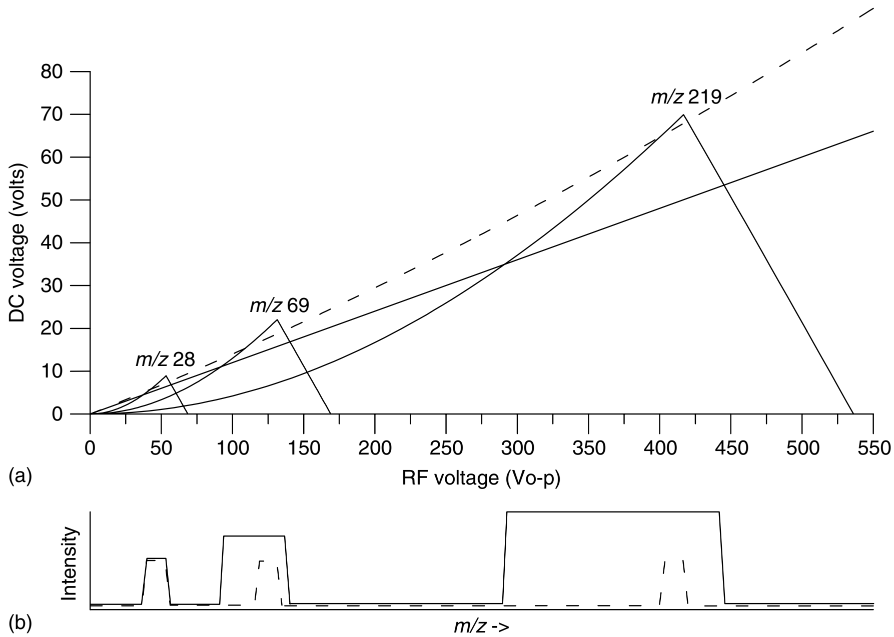

Figure 3 (a) Mathieu stability diagram for ions of *m/z* 28, 69, and 219. Two scan lines are shown, one dotted and a second solid. (b) Simulated mass spectra showing these ions as the RF and DC voltages are scanned along the two scan lines (dotted and solid) shown

mass filter. Typical values are 4 kV RF(0-p), 700 V DC, 1 MHz RF frequency, and 1 cm radius, and yield a mass-to-charge range of ~3000. As can be noted from equation (4), the Mathieu q parameter is proportional to the RF voltage and inversely proportional to (Constantopoulos *et al*., 1999; Pedder, 2002)

$$q_u = \frac{4eV}{m{r_0}^2\Omega^2} \tag{4}$$

the square of the inscribed radius and RF frequency; thus, the mass range of the mass filter can be increased by increasing the RF and DC voltages, or by decreasing the inscribed radius or RF frequency. The mass resolution is a function of the ratio of the RF and DC voltages (the slope of the scan line in Figures 2 and 3); increasing the slope to move the scan line closer to the apex of the stability region (moving from the solid line to the dotted line, for instance) increases the mass resolution, as shown in the spectra in Figure 3(b). Unfortunately, the increase in mass resolution is accompanied by a loss of sensitivity (decrease in transmission of ions through the mass filter). The ultimate resolution that can be achieved is determined not only by how close the scan line approaches the stability region apexes but also by the precision and accuracy of the quadrupole power supplies and the quadrupole rod dimensions.

An important operational mode of the quadrupole is achieved when U, the DC potential, is equal to zero ($a = 0$). This corresponds to a scan line along the x-axis in Figures 2 and 3. This RF-only mode results in transmission of ions of a very

wide range of *m/z* values, and is thus often termed "total ion mode" (Dawson and Douglas, 1999). Note that in this mode, there is a limit to the lowest *m/z* ion that can achieve a stable trajectory. This can be seen as the right-hand edges of the stability regions in Figure 3. This total ion mode is used for the collision cell in tandem quadrupole mass spectrometers, as discussed below; it is also often employed in quadrupoles used to help transmit ions from the ion source region to the quadrupole or other mass analyzer.

3. Tandem mass spectrometry

Most applications of mass spectrometry in proteomics employ mass spectrometry in tandem with one or more other analytical stages (Busch *et al*., 1998; Niessen, 1999). One of those stages is often a separation stage, typically liquid chromatography or capillary electrophoresis (Cole, 1997), leading to LC/MS and CE/MS, as discussed elsewhere in this volume (*see* Article 13, **Multidimensional liquid chromatography tandem mass spectrometry for biological discovery**, Volume 5). Another stage may be a second stage of mass spectrometry (the combination of two or more stages of mass spectrometric analysis in series is termed tandem mass spectrometry (McLafferty 1983; Fetterolf and Yost, 1983) or MS/MS, or even MS^n, where n can be ≥ 2). Indeed, a common approach in proteomics investigations is combining a stage of separation with tandem mass spectrometry, that is LC/MS/MS and LC/MS^n. These tandem (sometimes termed hyphenated) methods offer dramatically improved selectivity and information to solve tough analytical problems, as often encountered in proteomics.

Informing power is a figure of merit that provides a means of quantifying the amount of information available in such an analytical procedure. Fetterolf and Yost (1984) demonstrated the use of informing power to illustrate the advantages of hyphenated methods such as LC/MS/MS over single-stage analytical methods. Note that MS/MS is particularly important in LC/MS (compared to combined gas chromatography/mass spectrometry – GC/MS) for two reasons. First, LC typically provides much poorer chromatographic resolution than GC, meaning that LC separations are often incomplete, with coeluting peaks that MS/MS can help resolve. Second, LC/MS employs ionization methods such as ESI and APCI that provide only molecular-type ions and little or no structural information (GC/MS, in contrast, typically employs EI, which provides significant fragmentation and, therefore, structural information with only a single stage of mass spectrometry). Thus, LC/MS/MS is invaluable in providing structural information for the identification of components eluting from the LC column and for detecting those compound with high selectivity.

MS/MS is readily performed "tandem-in-space" (i.e., with two mass analyzers, typically quadrupole mass filters, in sequence). Note that MS/MS can also be performed "tandem-in-time", with two or more stages of mass analysis performed sequentially in time in a single ion trap such as a quadrupole ion trap (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5).

The triple quadrupole mass spectrometer (TQMS, see Figure 4) is the most common MS/MS instrument in use (Yost and Enke, 1979). The operational principles of the triple quadrupole tandem mass spectrometer can be described in a similar

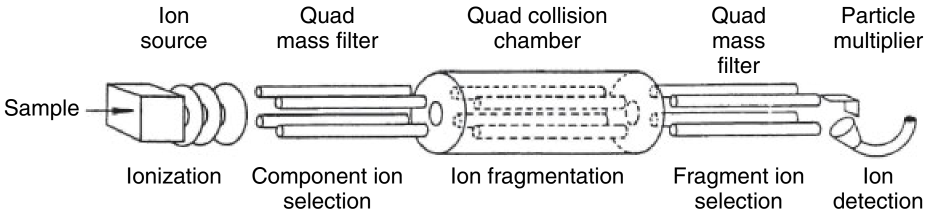

Figure 4 Schematic of a triple quadrupole mass spectrometer (TQMS)

fashion to the single quadrupole. Ions from the ion source enter the first quadrupole mass filter (Q1), which selects ions of a selected *m/z* and transmits them to the second quadrupole. The second quadrupole (Q2) functions as a collision cell in RF-only mode; CID is accomplished by adding a collision gas, typically nitrogen or argon, at a pressure of around 1–10 millitorr (1–10 microbar). The third quadrupole (Q3), another mass filter, provides a means of mass-analyzing the products of CID from the collision cell (Fetterolf and Yost, 1983).

Note that the RF-only quadrupole collision cell in triple quadrupole instruments is often replaced with a higher-order multipole (a hexapole or an octopole, with 6 or 8 rods, respectively) (McCloskey, 1990). The use of an RF-only higher-order multipole provides effective transmission of a wider mass range than an RF-only quadrupole. The stability diagram for a hexapole or octopole (as in Figure 2 for the quadrupole) has less well-defined stability boundaries, so the low-mass cut-off characteristic of an RF-only quadrupole is not an issue with higher-order multipole collision cells. A practical advantage that should be noted is that these multipoles require less demanding tuning procedures for the optimization of voltages and frequencies.

A fundamental understanding of the scan modes associated with the TQMS is essential for understanding the MS and MS/MS capabilities of the instrument. These are summarized in Table 1 (McLafferty, 1983; Fetterolf and Yost, 1983; Busch *et al*., 1998; Dawson and Douglas, 1999).

First, note that the triple quadrupole tandem mass spectrometer can readily be used to perform a single stage of mass spectrometry (MS) by setting two of the three quadrupoles into RF-only (total ion) mode. Either Q1 or Q3 can be used as a mass filter, scanned to obtain a full spectrum, or set to pass a single fixed *m/z* (or a few fixed *m/z* values), a mode termed selected ion monitoring (SIM). When Q1 and Q3 are both used as mass analyzers, there are four possible MS/MS scan modes. In the daughter ion scan mode (also called product ion scan), Q3 is scanned to obtain a spectrum of all the daughter ions generated by CID in q2 of the parent or precursor ion mass-selected with Q1. In the parent ion scan mode (also called precursor ion scan), Q1 is scanned to obtain a spectrum of all the parent ions that upon CID in q2 produce the daughter or product ion mass-selected with Q3. In a neutral loss scan, both Q1 and Q3 are scanned at the same rate but with a fixed difference in mass to detect only those ions that undergo a specific neutral loss in q2 such as a loss of mass 18 (H_2O). An important MS/MS scan mode for quantitating targeted compounds with maximum sensitivity is the selected reaction monitoring mode (SRM) in which one (or a few) selected parent-ion-to-daughter-ion transitions are

Table 1 MS and MS/MS operational modes of a triple quadrupole mass spectrometer, showing the modes for the two mass filters (Quadrupole 1 and Quadrupole 3) and the quadrupole collision cell (q2)

Scan mode	Q1	q2	Q3
MS – full scan[a]	Scan *m/z*	RF-only	RF-only
MS – selected ion monitoring (SIM)[a]	Fixed *m/z*	RF-only	RF-only
MS/MS – daughter ion scan	Fixed *m/z*	RF-only collision gas	Scan *m/z*
MS/MS – parent ion scan	Scan *m/z*	RF-only collision gas	Fixed *m/z*
MS/MS - neutral loss scan	Scan *m/z*	RF-only collision gas	Scan *m/z*[b]
MS/MS – selected reaction monitoring (SRM)	Fixed *m/z*	RF-only collision gas	Fixed *m/z*

[a]Note that the MS scan modes can be performed by mass selection with either Q1 or Q3, with the other one in RF-only (total ion) mode.
[b]Q3 scanned at a difference in mass corresponding to the mass of the selected neutral.

monitored by setting Q1 and Q3 to pass specific *m/z* values. SRM is the MS/MS scan mode analogous to the MS selected ion monitoring scan mode (SIM).

The relationship between the MS/MS scan modes can be explored by examining the plot of the three-dimensional MS/MS data – intensity (on a logarithmic scale) versus parent ion *m/z* versus daughter ion *m/z* – for a single compound, as shown in Figure 5 (Yost and Enke, 1979). Such a three-dimensional data set could be obtained by a series of daughter ion scans of each parent ion formed in the ion source, or by a series of parent ion scans of each daughter ion. It could even be obtained by a series of neutral loss scans for every possible neutral loss (i.e., by interrogating the surface in a series of lines parallel to the front line of the plot). Finally, a series of SRM experiments could measure the intensity of every possible parent ion–daughter ion pair (i.e., every point on the surface).

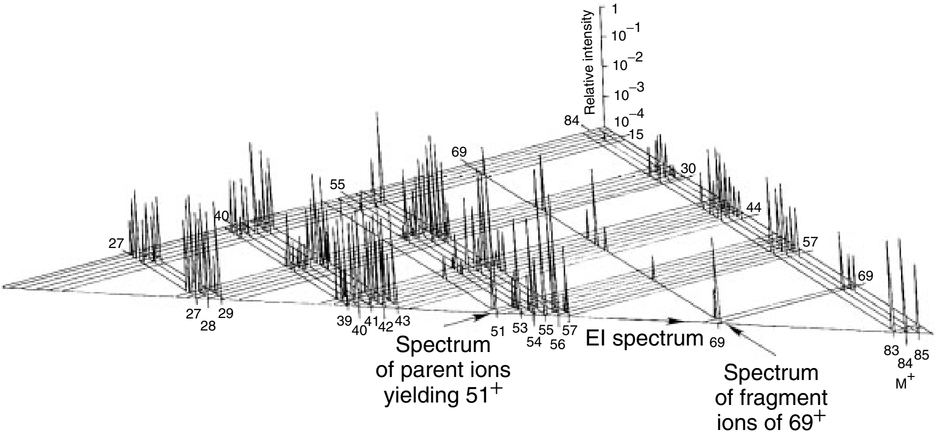

Figure 5 Plot of the three-dimensional dataset generated by electron ionization/MS/MS of cyclohexane. A similar plot of 1-propanol could be found in Fetterolf and Yost (1983)

Finally, note that all of these MS and MS/MS scan modes are readily achieved on a TQMS, and indeed, on most tandem-in-space MS/MS instruments. Note that this is not so on tandem-in-time MS/MS instruments, where the selection of a parent ion precedes (temporally, not spatially) the mass selection of the daughter ion. On tandem-in-time MS/MS instruments such as ion traps, parent scans and neutral loss scans are not available scan modes.

4. Conclusions

The quadrupole mass analyzer (and the RF-only quadrupole and multipole collision cells) enjoy a central role in the success of mass spectrometric methods in proteomics. Development of an understanding of the theoretical and practical aspects of quadrupoles can improve ones ability to utilize single and triple quadrupole mass spectrometers effectively to solve important problems in proteomics.

Short Specialist Review

Quadrupole ion traps and a new era of evolution

Jae C. Schwartz
Thermo Electron Corporation, San Jose, CA, USA

1. Introduction

For the first 30 years of their existence, three-dimensional (3D) quadrupole ion traps remained a specialty tool for a relatively few physicists and even fewer chemists (March and Hughes, 1989). These devices were ideal to study the fundamental properties of ions since the ions remained trapped in space for comparatively long amounts of time. Then in 1983, 30 years after their invention in 1953 (Paul and Steinwedel, 1960), a practical way of obtaining a mass spectrum of the ions contained in the device was discovered (Stafford *et al*., 1984). This subsequently led to the first commercial quadrupole ion trap mass spectrometer in 1984 (Syka, 1995) and put this technology in the hands of hundreds of analytical chemists. The early versions of this mass spectrometer utilized electron impact and chemical ionization, which occurred internally to the ion trap and allowed the analysis of gas phase samples including those eluting from gas chromatographs. In the early 1990s, with the advent of atmospheric pressure ionization techniques along with the ability to successfully inject ions into the trap from an external ion source, quadrupole ion trap mass spectrometers were developed for analytes in the condensed phase (Schwartz and Jardine, 1996; Bier and Schwartz, 1997) often coupled to liquid chromatographs (LC). These LCMS-compatible quadrupole ion traps have now emerged as powerful tools for the qualitative analysis of biological samples (Wagner *et al*., 2003), and so, now find widespread use in all fields of chemistry including biochemistry. The basis for the success of ion traps is due to their fundamental characteristics of performing rapid and efficient MS^n, along with their high sensitivity for producing full scan mass spectra. These two qualities, for example, result in producing sequence information on low amounts (attomoles) of a biological sample that can be processed to automatically identify the peptide or protein (Eng *et al*., 1994). Even with the current success of ion traps, a significant evolution in ion trap technology is currently taking place that promises to provide a significant leap in performance and therefore in the capabilities for biological and nonbiological applications.

2. Fundamental principles of operation

The physical structure of the 3D quadrupole ion trap is shown in Figure 1(a), and consists of three electrodes; a donut-shaped electrode called the "ring electrode" and two identical electrodes called "end-cap" electrodes, which have a single hole for ions to enter and exit the device. The surfaces of all three electrodes have a hyperbolic profile, which is required in order to generate the desired quadrupole electric field. Now, basic physics (Laplace equation of electrostatics) says that it is impossible to create a static electric field that would trap ions in all three dimensions. Consequently, an alternating electric field is used by applying a radio frequency (RF) voltage to the ring electrode. This voltage creates a RF trapping field in all three dimensions. The average effect of the RF trapping field continuously pushes ions to the center of the device. With the assistance of helium gas introduced into the trap, ions occupy a roughly spherical volume in the center of the device. Collisions with helium reduce the kinetic energy of the ions reducing the cloud size, resulting in increased sensitivity and resolution of the resultant mass spectrum. The helium also serves as a collision gas for dissociation of ions when their kinetic energy is purposely increased. As a simplification, trapped ions can be thought to have nearly simple sinusoidal motion while stored, with frequencies of this motion being inversely related to their m/z. Once a population of ions is trapped, the method that produces their mass spectrum consists of scanning the amplitude of the RF voltage over a certain range linearly with time while applying an additional resonance ejection voltage across the end caps (Syka and Louris, 1988). Ions are ejected as the ion frequency of motion matches the applied resonance signal because of the RF amplitude being changed. This results in ions being ejected from the trap through the end-cap apertures in order of their m/z ratio and are detected. Since there is a direct relationship of the m/z of an ion and the RF amplitude at which it will be ejected, acquiring the signal response while the RF amplitude is ramped produces a mass spectrum.

With the understanding of these basic principles, a typical operational sequence can be considered. First, the ions are formed within or are introduced into the trap.

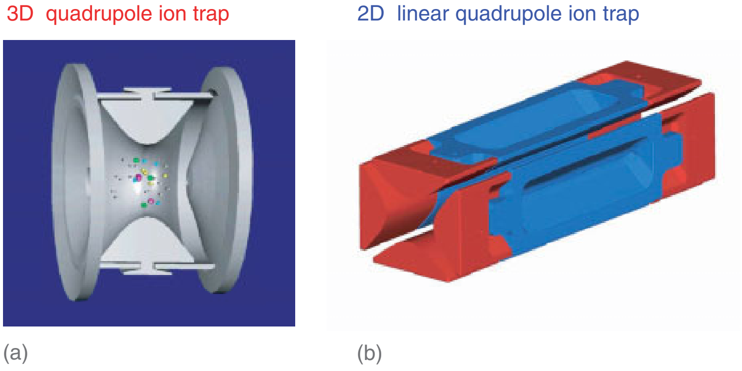

Figure 1 (a) Three-dimensional ion trap structure with ring electrode and two end-cap electrodes. (b) Two-dimensional linear ion trap with four parallel rods cut into three sections

Most modern traps inject ions from an external ion source. This process is somewhat challenging since the ions must penetrate the RF field as they pass through the injection end-cap aperture. As a result, only some fraction of the entering ions is trapped. To compensate, however, simply increasing the accumulation time can assure that the ion trap is full to its capacity. This ability to accumulate ions is a unique feature of trapping-type instruments and helps increase sensitivity and lowers the limits of detection. After a population of ions is trapped, they can then be manipulated in many ways. One example is to isolate an ion of a particular m/z (or range of m/z values) while all others are ejected from the trap. Isolation can be accomplished by many different methods, a common one consisting of applying a multifrequency resonance ejection waveform (Louris and Taylor, 1993). The resulting isolated ions can then be dissociated into fragment ions using a resonance excitation process, which energetically collides the ions with helium atoms (Syka and Louris, 1988). The sequence of isolation and activation of ions can be performed an arbitrary number of times, hence, MS^n, and is another distinctive feature of ion-trapping instruments. When a spectrum of the ions contained in the trap is desired, the RF amplitude is ramped along with the resonance ejection voltage and the ions are ejected to the detector, as was described above. The resultant MS/MS or MS^n spectrum provides characteristic structural information on the isolated precursor ions.

It is inherent in this operational sequence that ion trap mass analyzers have a high duty cycle, and therefore high sensitivity, even for full scan mass spectra. This is due to the fact that the entire spectrum is obtained on the same population of ions whether performing full scan MS or MS^n. In most commercial ion trap systems, the ion accumulation times are automatically controlled to optimize the number of ions analyzed and to minimize space charge effects. As a consequence, as the sample level decreases, the duty cycle actually increases. This is in contrast to beam type mass analyzers, such as quadrupole mass filters that have high duty cycles only when monitoring a single selected ion mass but have very low duty cycles for full scan modes since each m/z scanned requires new ions from the ion source.

3. A new evolutionary era: 2D linear traps

Although 3D quadrupole ion trap mass spectrometers have been extremely successful, their performance has some fundamental limitations. Space charge effects are the Achilles heel of all ion-trapping instruments. By definition, 3D ion traps have RF electric fields containing the ions in all three dimensions. As a consequence, only so much total ion charge can be contained in the ion cloud before space charge effects degrade the quality of the mass spectrum, including mass accuracy and resolution. Thus, one inadequacy in 3D ion traps is that the charge capacity is quite limited ($\sim$1000 charges). A second fundamental limitation is the trapping efficiency of injected ions. As was mentioned above, injected ions must penetrate the RF electric field and, therefore, ions are successfully trapped only during a narrow phase window of the oscillating RF voltage. These limitations argue the need to remove the RF electric field in one of the dimensions of the device, resulting in a 2D or linear ion trap. The removal of the RF field in one

dimension allows the ion cloud to expand from the approximately spherical shape to more of a cylindrical shape of some arbitrary length, resulting in increased charge capacity. In addition, since ions can be injected on the axis without the RF field, the trapping efficiency is significantly increased. A picture of the 2D device is shown in Figure 1(b) and can be contrasted to the 3D trap. This device consists of four parallel rods cut into three sections and has slots in two of the center section rods for the ions to exit. The ions are trapped radially by an RF containment field but are trapped axially by a static electric field. The results of such a device even with a moderate length of less than 2.5 in gives improvements of trapping efficiencies of more than 10-fold and increased storage capacity of more than 20-fold (Schwartz *et al*., 2002). These increases directly translate to increased sensitivity, lower limits of detection, increased dynamic range, and enhanced MS^n performance.

An additional advantage of the 2D linear trap involves higher detection efficiencies. In a 3D trap, since ions are injected through one end cap, but are typically ejected through both end caps equally, normally only one detector can be used. Consequently, not all trapped ions are detected. Since the ions are injected into the 2D trap orthogonal to the axis of detection, two detectors can be utilized to detect twice as many ions as in the 3D trap. This increases the number of detected ions by an additional factor of two and, therefore, a total of 40 times more ions can be detected in each scan.

The resultant performance increase of the 2D linear trap can be demonstrated in a simple example, namely intact proteins. Intact proteins are challenging for ion traps since each protein ion upon electrospray ionization (ESI) will contain many charges and, therefore, will severely limit the actual number of ions that can be analyzed before space charge effects occur. Figure 2(a) shows the ESI mass spectrum of the protein myoglobin having an average molecular weight of 16 950 a.m.u., obtained on a 3D ion trap. A single scan is shown, which includes the various charge states of the protein molecules. In order to identify the molecular weight of the protein, the spectrum containing the different charge states can be deconvoluted to convert the m/z spectrum into a true mass spectrum, shown in the lower spectrum of Figure 2(a). Owing to the limited charge capacity, and that each molecule has an average of 16 charges, it is difficult to identify the molecular weight of the protein because of the low signal-to-noise ratio of the spectrum. Scans can be averaged to increase the quality of the spectrum; however, this takes substantially more time. This is in contrast to the single spectrum obtained on the 2D linear trap shown in Figure 2(b). Owing to the higher trapping efficiency, higher charge capacity, and higher detection efficiency, this single spectrum is comparable to an average of more than 20 scans using a 3D trap. The molecular weight of the protein is clearly identified in the lower deconvoluted mass spectrum.

4. Data-dependent analyses: maximizing the yield of information

Switching from MS to MS/MS or to MS^n has always been relatively simple and fast on ion traps compared to other instruments. Consequently, development of

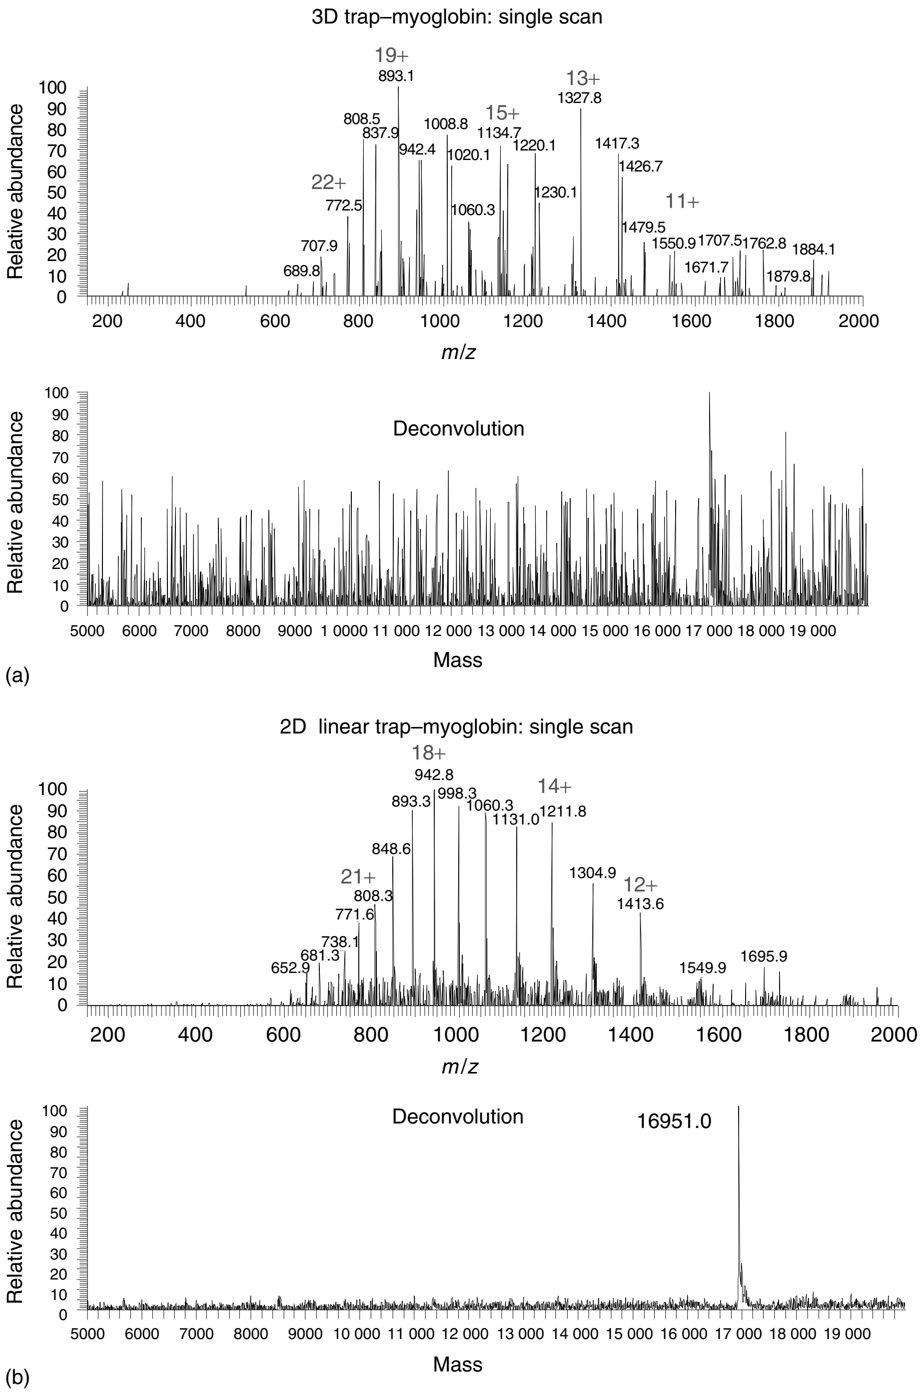

Figure 2 (a) Electrospray ionization mass spectrum of intact myoglobin using a 3D ion trap. (b) Electrospray ionization mass spectrum of intact myoglobin using a 2D linear ion trap

automatic and data-dependent scanning methods has been carried out on these systems and has emerged as "the" technique for yielding maximum information from complex samples (Wenner and Lynn, 2004). A typical method is one where the system first takes a full scan mass spectrum. It then determines the three most intense components in the spectrum and automatically performs MS/MS on each precursor ion, producing structural information for the three selected ions. On the next MS scan, the system can ignore ions already analyzed by MS/MS and search for three new ions in the mass spectrum to perform MS/MS or MS^n on. Many different criteria can be specified to trigger the acquiring of MS/MS spectra besides simply intensity. As just a few examples, the system could require a certain intensity ratio of two ions that exist in the MS scan for use with labeled or tagged analytes, and/or the ions must have a certain charge state, or must be below or above certain intensity thresholds. In one method, the system looks for the loss of phosphoric acid from phosphorylated peptides in the MS/MS spectra. If the loss occurred, then MS^3 is performed on this new ion. This method not only identifies the peptide as a phosphopeptide but can also determine the site of phosphorylation (Zumwalt *et al*., 2003). These data-dependent type of methods can generate a tremendous amount of information. Currently, for peptide and protein identification, the data is processed using two basic approaches. One approach makes use of databases of known peptides and proteins to which the data is compared to in order to produce a likely identification (Mann *et al*., 2001), while a de novo approach attempts to identify the sequence of a sample that may not be known (Zhang and McElvain, 2000). The sensitivity and usefulness of these methods on ion traps is demonstrated in Figure 3(a) and (b). Just 40 attomoles of a myoglobin tryptic digest was injected and separated on a 170-um packed capillary LC column. The mass chromatogram for the peptide at m/z 690 is shown in Figure 3(a) along with the MS spectrum indicating the two charge states of the peptide ion. The MS/MS spectrum of the doubly charged peptide ion obtained automatically by the data-dependent method is shown in Figure 3(b), and yields nearly the complete sequence of the peptide, allowing automatic identification of the peptide and the protein myoglobin using data base searching tools.

Although not fundamental to the technology, other enhanced capabilities have been implemented on the newer 2D linear trap technology (Schwartz *et al*., 2002). The 2D linear trap has the ability to obtain resolutions greater than 30 000 by slowing down the rate of scanning out the ions from the trap. This resolution is sufficient to help unambiguously determine the charge states of ions by the spacing of their isotope peaks in the mass spectrum and also to separate isobaric ions. The overall higher resolutions obtainable can also be traded off for increased scan rates to further reduce analysis time and therefore increase the number of experiments performed in a given time. Another major advantage of this technology, which is certain to promote further developments, is that the mechanical geometry has the advantage of having the back end of the device free from detectors, making this device ideal for coupling to other devices including other mass analyzers in hybrid configurations (*see* Article 10, **Hybrid MS**, Volume 5). One form of linear trap is incorporated as the third quadrupole in a triple quadrupole instrument (Hager, 2002). Another extremely powerful configuration now available combines a 2D linear trap with a Fourier transform mass spectrometer (Horning, *et al*., 2003). This hybrid instrument

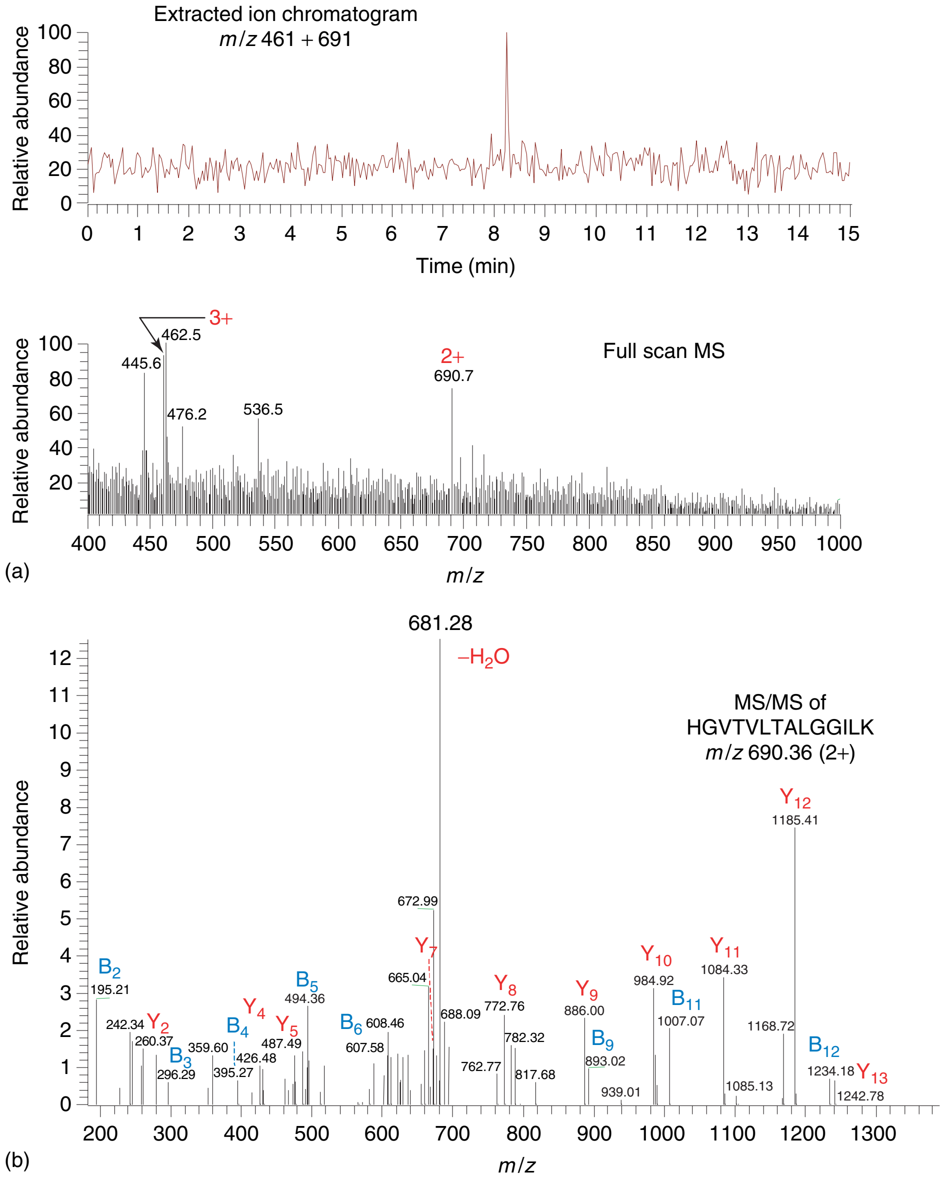

Figure 3 (a) Extracted ion chromatogram showing elution of one peptide from 40 attomoles of myoglobin digest and the mass spectrum at that retention time. (b) The MS/MS spectrum of the peptide showing virtually complete sequence information and allowing automatic peptide and protein identification

not only retains all the functionality of the 2D linear trap but can also give 1-ppm mass accuracies and >100 000 resolution scanning at 1 scan/s. Other hybrids or combinations of devices including ionization techniques can easily be imagined, opening the doors to a vast amount of future capabilities to even further enhance ion traps' usefulness for real-world complex mixture component analysis.

Short Specialist Review

Hybrid MS

R. H. Bateman and J. I. Langridge
Micromass UK Ltd, Manchester, UK

1. Hybrid MS instruments

Tandem mass spectrometry, or MS/MS, has become the preferred technology for many applications in which mass spectrometry plays a part. First, tandem mass spectrometry allows selection and isolation of specific compounds of interest and their subsequent identification. Second, the extra selectivity of MS/MS enables this technology to be used for quantification of target compounds, even in the presence of complex matrices.

There are several different types of mass analyzers that are commercially available. These different mass analyzers have different characteristics that make them more or less suitable for certain applications. Hybrid MS instruments consist of two mass analyzers in series and a means for fragmenting selected ions, usually positioned after the first mass analyzer and before the second. The means for fragmenting ions is most commonly that of promoting collision-induced decomposition (CID) in which ions undergo collisions with gas molecules in a partially enclosed collision cell. In most hybrid MS instrumentation, the processes of mass selection, fragmentation, and product ion mass analysis take place sequentially in space. The first mass analyzer (MS1) may be used to select ions of a target compound, the CID gas collision cell to fragment those ions, and the second mass analyzer (MS2) to analyze the products of the fragmentation process. In some instances, fragmentation can take place in one or other of the mass analyzers. Here one or more of the processes of mass selection, fragmentation, and product ion mass analysis can take place sequentially in time.

Different combinations of mass analyzers also have different characteristics that make them more or less suited for certain applications. It is possible to combine most types of mass analyzers in almost any sequence, and numerous combinations have been constructed. Table 1 lists the available types of mass analyzers and those combinations that are most commonly used for MS/MS applications.

The following is a brief description of those hybrid instruments that are most commonly used for studies in the life sciences, and their principal areas of application.

Table 1

MS1	MS2					
	Magnetic sector	Quadrupole filter	Quadrupole trap	Axial TOF	Orthogonal TOF	FT-MS
Magnetic sector	✓	✓	✓	✓	✓

✓✓Hybrid combinations that are available and are most commonly used for studies in the life sciences.

2. Triple quadrupole (Q-CID-Q)

In the triple quadrupole tandem mass spectrometer, MS1 is a quadrupole mass filter (*see* Article 8, **Quadrupole mass analyzers: theoretical and practical considerations**, Volume 5) followed by a gas collision cell and then by MS2, which is again a quadrupole mass filter. The name "triple quadrupole" is derived from the first such instrument in which an RF quadrupole was used to guide ions through the gas collision cell. The quadrupole mass filter is typically used to transmit ions of a single m/z value. Therefore, to record a full mass spectrum, the quadrupole must be scanned across the full m/z range to sequentially transmit ions of different m/z values. The duty cycle for this process is quite low, and as a consequence, the sensitivity of a quadrupole mass filter used to record a full spectrum is relatively poor. On the other hand, the quadrupole mass filter will have 100% duty cycle when used to transmit ions of a single m/z value. The triple quadrupole used for selected reaction monitoring (SRM), in which it is used to transmit ions of a single precursor in MS1 and ions of a single product in MS2, is very specific and exceptionally sensitive. Therefore, triple quadrupoles have found significant use in the drug development process where they are used in the SRM or MRM (multiple reaction monitoring) modes to quantify target compounds of biological significance.

A common application in peptide and protein analysis for the triple quadrupole makes use of the "precursor ion scanning" mode. In this mode, MS2 is set to transmit a specific characteristic product ion, while MS1 is scanned to sequentially transmit precursor ions into the gas cell for fragmentation. When the specific product ion is detected, then the precursor ion mass transmitted by the quadrupole is recorded. This approach has proved particularly useful in the analysis of protein post-translational modifications, such as phosphorylation and glycosylation.

3. Quadrupole–quadrupole trap (Q-CID-Q/Trap)

A derivation from the triple quadrupole tandem mass spectrometer is the arrangement in which the MS2 quadrupole mass filter is substituted with a linear

quadrupole ion trap (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5). In addition to the normal attributes of the triple quadrupole, the MS2 linear quadrupole ion trap provides some greater flexibility for qualitative applications. This arrangement allows trapping of precursor or fragment ions in the MS2 linear quadrupole ion trap with subsequent mass selective axial ejection, thus improving full scan MS or MS/MS sensitivity over the triple quadrupole mass spectrometer. The linear quadrupole ion trap can also be used to enhance the relative abundance of certain fragment ions and the abundance of multiply charged ions relative to that of singly charged ions.

4. Quadrupole trap–axial time-of-flight (Trap/CID-TOF)

In this tandem MS/MS arrangement, MS1 is a conventional 3D quadrupole ion trap (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5) and MS2 is an axial time-of-flight (TOF) mass spectrometer (*see* Article 7, **Time-of-flight mass spectrometry**, Volume 5). The quadrupole ion trap is also used as the collision cell for fragmentation of precursor ions selected by the ion trap. The TOF mass spectrometer incorporates a reflectron to improve mass resolution and mass accuracy. This combination has been primarily coupled with MALDI (*see* Article 11, **Nano-MALDI and Nano-ESI MS**, Volume 5). The insertion of the quadrupole ion trap between the MALDI source and TOF mass spectrometer decouples these elements so that mass resolution and mass calibration is no longer dependent on variations in the MALDI source conditions. This arrangement allows MS^n experiments to be carried out in the quadrupole ion trap, with the fragments ejected and mass measured using the axial TOF. This provides MS^n capabilities on an instrument that can obtain mass measurement accuracy of better than 10 ppm. The MS^n and accurate mass capabilities of this instrumentation allow its use for peptide and protein identification.

5. Time-of-flight–time-of-flight (TOF-CID-TOF)

In this instrument, a MALDI ion source is coupled with an axial time-of flight mass analyzer (MS1), and can be used to select precursor ions for fragmentation in a gas cell. Fragmentation may also occur by post source decay (PSD). Mass analysis of the fragment ions produced is then accomplished by further acceleration of product ions into a second axial time-of-flight mass analyzer (MS2). The MS2 mass analyzer incorporates a reflectron (*see* Article 7, **Time-of-flight mass spectrometry**, Volume 5). This and the use of appropriately timed acceleration fields in one or both TOF mass analyzers provide improved resolution and mass measurement accuracy on the fragment ions than may be obtained in a traditional PSD experiment on a conventional TOF instrument. These instruments are targeted at "high-throughput" protein identification studies.

6. Quadrupole–orthogonal time-of-flight (Q-CID-TOF)

This hybrid MS/MS instrument includes a quadrupole mass filter (MS1), followed by a gas collision cell for fragmentation of selected ions, and finally, an orthogonal

acceleration time-of-flight (TOF) mass spectrometer (MS2) for recording mass spectra. The orthogonal TOF mass spectrometer (*see* Article 7, **Time-of-flight mass spectrometry**, Volume 5) has a number of advantages over a scanning quadrupole mass filter. The orthogonal TOF will repetitively extract a portion of a continuous ion beam and will record the full mass spectrum. The speed of acquisition, sensitivity, mass resolution (>15 000 FWHM), and mass accuracy (<5 ppm RMS) are all considerably higher than for a scanning quadrupole mass filter. As a consequence, it is normal practice to use the TOF mass spectrometer for acquisition of both precursor ion and product ion mass spectra. Precursor ion spectra are acquired by operating the quadrupole in the RF (nonresolving) mode so that the total ion flux is transported to the orthogonal TOF for mass analysis. Switching to MS/MS only requires switching the quadrupole into the resolving mode at the required precursor ion mass and raising the collision energy appropriate to that for the selected mass and charge of the precursor ion. This hybrid combination does not offer the sensitivity to match that of a triple quadrupole in the SRM or MRM modes of operation. On the other hand, it provides excellent sensitivity, speed, and selectivity that make it particularly well suited for qualitative applications. It is most commonly used for the identification of unknowns from the exact mass measurement of the precursor ion and its product ions. This hybrid configuration is one of the preferred arrangements not only for the identification of peptides and proteins but also for the identification of metabolites and other small molecules of biological significance.

7. Quadrupole trap–orthogonal time-of-flight (Q-CID/trap-TOF)

This hybrid MS/MS configuration is similar to the previously described quadrupole–orthogonal TOF combination other than the linear quadrupole in the gas collision cell is additionally used to trap ions. In addition to the attributes of the quadrupole–orthogonal TOF combination, this arrangement has the capability to increase the duty cycle of the orthogonal TOF over a narrow mass range, albeit at the cost of reduced duty cycle outside that mass range. This is achieved by temporarily trapping ions in the quadrupole gas cell, releasing them, and pulsing the orthogonal TOF accelerating field such as to synchronize with the arrival of ions of interest. This increases the duty cycle, and hence sensitivity, for those ions. This can be advantageous for certain applications in which, for example, a specific daughter ion species is of interest. As with the "precursor ion scanning technique" on a triple quadrupole, this approach can be useful in the analysis of protein post-translational modifications, such as phosphorylation and glycosylation.

8. Quadrupole–Fourier transform ICR-MS (Q-CID-FTMS)

This hybrid MS/MS instrument consists of a quadrupole mass filter as MS1, followed by a gas collision cell for fragmentation of selected ions, and finally, a

Fourier Transform Ion Cyclotron Resonance (FT-ICR) or Fourier Transform Mass Spectrometer (FTMS) as MS2 for recording of mass spectra (*see* Article 5, **FT-ICR**, Volume 5). This has similar characteristics to that of the quadrupole–orthogonal TOF combination, other than that the TOF is replaced with an FTMS. Modern FTMS systems, employing superconducting magnets with field strengths in the region of 7 to 12 Tesla, are capable of very high resolution (>100 000 FWHM) and mass accuracy (<2 ppm RMS). As with the quadrupole–orthogonal TOF combination, the FTMS can be used for recording both precursor ion and product ion mass spectra.

9. Quadrupole trap–Fourier transform ICR-MS (Trap/CID-FTMS)

This hybrid MS/MS combination incorporates a linear quadrupole ion trap (MS1), which also functions as a gas collision cell for fragmentation of selected ions, and an FTMS (MS2) for recording of mass spectra. This configuration has very similar characteristics and advantages to that of the quadrupole mass filter–FTMS combination. However, the linear quadrupole ion trap also allows mass selective radial ejection to separate ion detectors. This offers a number of additional advantages.

First, the linear quadrupole ion trap may be used for recording product ion spectra with higher sensitivity, albeit at reduced mass resolution and mass accuracy.

Second, the inherent dynamic range of the FT-ICR trap is quite limited; it requires an optimum number of ions for optimum mass accuracy. The linear quadrupole ion trap can be used to accumulate approximately the required number of ions before transferring them to the FT-ICR cell. This technique effectively extends the dynamic range for this type of hybrid MS/MS mass spectrometer.

Third, the measurement time required by the FTMS can be quite long if the highest mass resolution is required. The linear quadrupole ion trap may be used to acquire product ion spectra while simultaneously acquiring the highest mass resolution precursor ion spectrum with the FTMS.

As for the conventional 3D quadrupole ion trap, daughter ions with m/z values less than about 25 ∼ 33 % of the precursor ion m/z value are unstable in the linear quadrupole ion trap, and are not recorded. However, the linear quadrupole ion trap can be programmed to acquire MS^n spectra.

Short Specialist Review

Nano-MALDI and Nano-ESI MS

Gyorgy Marko-Varga, Johan Nilsson and Thomas Laurell
Lund University, Lund, Sweden

1. Introduction

In line with the rapid development of miniaturized and chip-integrated approaches to analytical and bioanalytical systems, the proteomics work scheme has also been the focus of dimensional reduction. The driving arguments for miniaturization are seen in the possibilities of improved sample throughput, reduced sample volume requirements, lower reagent costs, and improved limits of detection (Reyes *et al*., 2002; Auroux *et al*., 2002). In recent years, the analytical endpoint in proteomics has to a great extent become dominated by mass spectrometry and database matching. In this time, laser desorption ionization (MALDI) and electrospray ionization (ESI) have become the two major techniques to ionize the target species prior to time-of-flight separation based on mass and charge (James, 2000). The aspects on miniaturization in this field have, to a great extent, taken the course of optimizing the sample handling and processing steps prior to the MS readout (Marko-Varga *et al*., 2004).

2. Miniaturization in MALDI-TOF MS

An inherent bottleneck in MALDI-TOF MS has been the transfer of the proteomic sample from, for example, a microtiter plate format to the mass spectrometry target plate. The MS instrumentation was, and still most are, not equipped with an MS target plate loader that can handle the dimensions of a 96-well format. As the industry sample-handling robotics follows the dimensions of the 96-well standard format, a sample transfer and format change from the well plate to the MALDI-target is a request. Recent developments have demonstrated that miniaturized protocols to deposit proteomic samples may provide improved analytical performance in the proteomic work scheme such as increased sample throughput (Ekström *et al*., 2000; Little *et al*., 1997), continuous or semicontinuous MALDI-readout from micro liquid chromatography separations (Preisler *et al*., 1998; Preisler *et al*., 2002; Miliotis *et al*., 2000; Wall *et al*., 2002).

A general strategy employed in the protocols for sample handling on the MALDI target has followed the findings reporting that reduced sample spot size provides

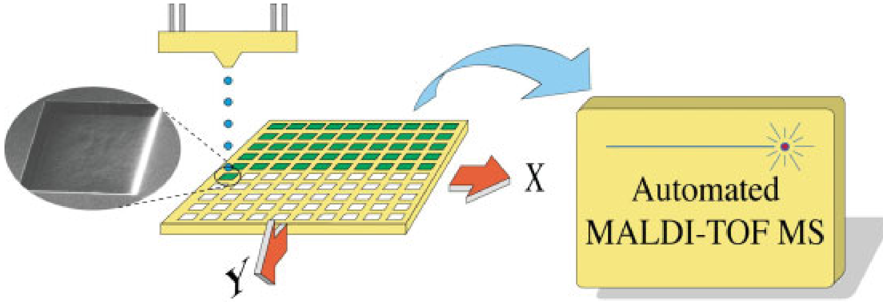

Figure 1 Principal setup for nanovial sample deposition prior to MALDI-TOF MS readout

increased sensitivity in the MS readout (Ekström *et al*., 2000; Gobom *et al*., 1999; Önnerfjord *et al*., 1998). This has also been realized in commercial systems such as the MicroMass, MassPrep^{TM} MALDI-Target, and the so-called anchor point MALDI targets by Bruker Daltonics GmbH, Germany (Schuerenberg *et al*., 2000). Work on further miniaturization and controlling the confinement of the sample to a predefined spot was demonstrated by Ekström *et al*. (2001a) using in-house developed piezoelectric dispensing for controlled deposition of the sample and also silicon microfabricated MALDI target plates to confine the deposited fluid by means of surface tension forces in the so-called on-spot enrichment. Later, this was also demonstrated on disposable polymer nanovial target plates (Marko-Varga *et al*., 2001; Ekström *et al*., 2001b). Figure 1 shows the principal setup for piezoelectric sample deposition and confined sample deposition in nanovial target plates. More recently, a stand-alone system for automatic sample transfer from chip-integrated solid-phase extraction microarrays has been realized (Wallman *et al*., 2003). The sample is transferred from the solid-phase microextraction chip to the microdispenser solely by means of capillary forces (i.e., no external pumping is needed to drive the sample flow through the microchips for subsequent piezoelectric deposition onto a MALDI target plate). The chip-based sample handling protocol provides both sample enrichment and cleanup performed in two steps; (1) microchip solid-phase enrichment and (2) on-spot enrichment, that is, a dual-enrichment mode is obtained that offers a sensitivity increase, superseding conventional MALDI sample preparation protocols (Wallman *et al*., 2004).

3. Miniaturization in ESI-MS

Interfacing chip-integrated protocols to electrospray ionization mass spectrometry (ESI-MS) has been a long-sought goal and several promising approaches have emerged lately. A key issue in this development has been the microfabrication of an electrospray tip that provides both the necessary microfluidic and electrostatic features. The early chip/ESI work demonstrated electrospray directly from the end piece of a microchip with an embedded microchannel (Xue *et al*., 1997; Ramsey and Ramsey, 1997; Kameoka *et al*., 2001). As the flat front surface of the chip side does not provide an optimal zone for building up a reproducible Taylor cone to generate a stable electrospray, much effort has been put into the development of

a microtechnology fabrication process for nanoelectrospray tips. The strategy has therefore been to limit the spreading of the effluent at the ESI-point by extending the microchannel beyond the bulk material of the chip. The insertion of a conventional capillary or regular ESI-tip at the chip termini is a common approach (Figeys and Aebersold, 1998; Bings *et al*., 1999), though not very amenable to low-cost mass fabrication.

With the advent of deep reactive ion etching (Clerc *et al*., 1998), silicon microfabrication could offer engineering tools for out-of-plane high-aspect ratio and high-fidelity microstructures, which basically corresponds to the geometries needed for making a good ESI-tip. Advion BioSciences Ltd., Ithaca, NY, USA, currently offers chip-based ESI-tips fabricated as fine cylindrical pipes in an array format using silicon micromachining (Van Pelt *et al*., 2003a,b). This design has proven to be reproducible and sufficiently robust for automated ESI applications. A similar design was later proposed by the group of Stemme, presenting a slight modification of these tips with a reduced front surface area and thereby claiming improved ESI conditions (Griss *et al*., 2002). Silicon microfabricated devices do not offer single-use components owing to the production costs associated with clean room manufacturing and, consequently, much interest has lately been put into the development of disposable polymer ESI-tips. This development also follows the trends of biochip developments where low-cost polymer chips have gained much attention recently (Ng *et al*., 2002). In line with this, Craighead *et al*., proposed a polymer-based chip-integrated ESI interface based on a triangular polymer lip extending from the microfluidic chip, guiding the sample from the exit of the chip to the point of Taylor cone formation (Kameoka *et al*., 2002). This approach seems like a very reasonable and low-cost solution to the problem of controlling the fluid in the high-voltage field at the chip exit of ESI. An alternative ESI interface, equally interesting from a scientific as well as commercial point of view was demonstrated by Killeen *et al*., Agilent Technologies Inc., Paolo Alto Ca, USA, with a complete system fabricated in laminated polyimide sheets that holds both a micro LC column and upstream interface to conventional rotary valves for sample injection and eluent control (Killeen *et al*., 2003). The chip outlet is defined as a fine laser-cut tip at the end of the separation channel, providing a robust and simple ESI interface. It should be noted that this design offers both on- and off-chip interfacing, which commonly is not the case in regard to lab-on-a-chip systems. This means that conventional high-fidelity analytical techniques can be linked upstream to the chip-integrated sample processing.

4. Conclusions

Ongoing research within miniaturization strategies of mass spectrometry sample handling and processing indicates that we currently are in a transition stage where commercial initiatives at an increasing pace now are entering the arena. The field of lab-on-a-chip, micro total analysis systems, BioMEMS, and nanobiotechnology have now reached a level of maturity where the major interdisciplinary bridging of knowledge is at hand. Also, fundamental material science developments have advanced sufficiently to provide the fruitful environment needed to be able to

successfully address the questions raised in a bioanalytical situation utilizing MEMS and nanotechnology principles and methodologies. It can be anticipated that we are facing a prosperous future with rapid and dramatic improvements in sample preparation, and handling for mass spectrometry on the basis of novel miniaturized concepts, offering both improved sample throughput, sensitivity, and reduced sample volume requirements.

Protein fingerprinting

David Fenyo
GE Healthcare, Piscataway, NJ, USA

1. Introduction

Identification of proteins by searching protein sequence collections with peptide mass fingerprinting data is widely used (Figure 1). The proteins in the sample are first separated to obtain one or a few proteins of interest. These proteins are then digested with a proteolytic enzyme. Mass spectra of the resulting peptide mixtures are acquired. The mass spectra are processed to find the masses of the peptides in the mixture. These measured masses are compared with calculated peptide masses for each protein in a protein sequence collection according to the rules defined by a set of user-defined parameters (Figure 2). A score is calculated for each comparison and the protein sequences in the collection are ranked according to the calculated score. Different search engines calculate the score in different ways (Henzel *et al*., 1993; Mann *et al*., 1993; Pappin *et al*., 1993; Yates *et al*., 1993; James *et al*., 1993; James *et al*., 1994; Wilkins *et al*., 1998; Perkins *et al*., 1999; Clauser *et al*., 1999; Berndt *et al*., 1999; Gras *et al*., 1999; Zhang and Chait, 2000; Gay *et al*., 2002; Eriksson and Fenyo, 2004a; Samuelsson *et al*., 2004; Rognvaldsson *et al*., 2004; Magnin *et al*., 2004; Levander *et al*., 2004). The meaning of these scores is in general not easily understood by the nonexpert user and they are not amenable to automation. Therefore, an additional step is necessary to test the significance of the results and convert the search engine–dependent score into a measurement of the significance of the protein identification result.

The problem of comparing the experimental mass spectra with calculated peptide masses for a protein sequence collection has been solved with different approaches in the different search engines. However, all search engines calculate a score for ranking the proteins in the sequence collection. The best matching protein sequence has the highest probability of being present in the sample that was analyzed and it is therefore ranked highest. The most widely used search engines are Mascot (Perkins *et al*., 1999), ProFound (Zhang and Chait, 2000), and MS-Fit (Clauser *et al*., 1999). For an evaluation of the performance of the different peptide mass fingerprinting algorithms, see Chamrad *et al*. (2004).

This paper will discuss how different search parameters influence the results and how the search engine–dependent scores can be converted into a measurement of the significance of the protein identification result.

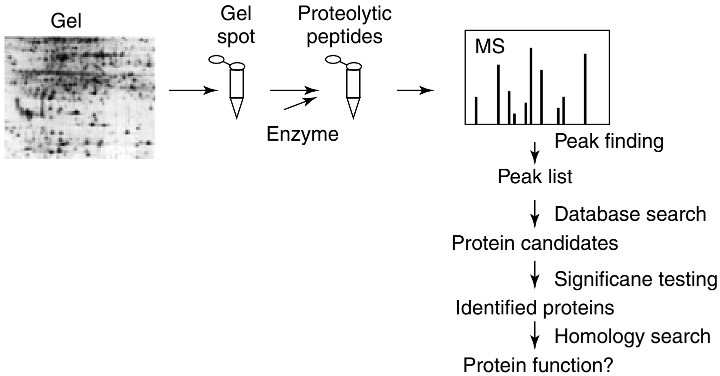

Figure 1 Protein fingerprinting is typically performed by first separating the proteins followed by enzymatic digestion and mass analysis. The raw mass spectra are subsequently analyzed to obtain a list of peptide masses. This peptide mass map is then searched against a protein sequence collection and the significance of each protein candidate is tested

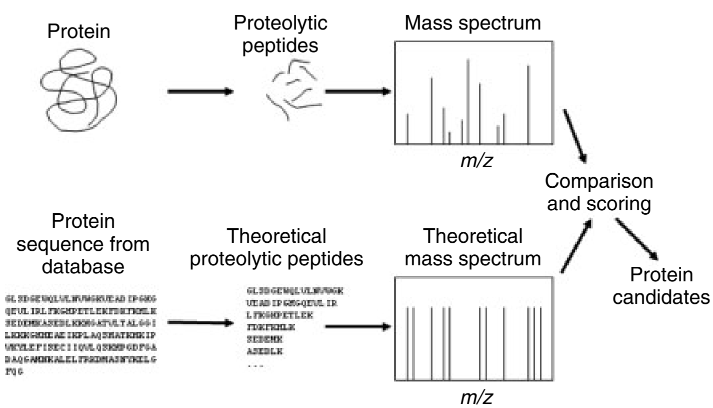

Figure 2 Searching a sequence collection with peptide mass fingerprinting data is performed by mimicking the experiment in silico: each entry in a protein sequence collection is theoretically digested using the same specificity as the enzyme used in the experiment. A theoretical mass spectrum is constructed, compared with the measured mass spectrum. The entries in the protein sequence collection are ranked according to how well they match the experimental data

2. Significance testing

One of the critical steps in protein identification is significance testing (Eriksson and Fenyo, 2004a; Eriksson *et al*., 2000; Eriksson and Fenyo, 2002; Fenyo and Beavis, 2003; Eriksson and Fenyo, 2004b). False identifications are possible due to random matching between the measured and calculated masses. In the result of a search of a sequence collection with peptide mass fingerprinting data, there will always be a highest ranked protein sequence. This protein sequence might correspond to a protein that is in the sample analyzed or simply be a false-positive, that is, get the highest score because of random matching between the calculated and

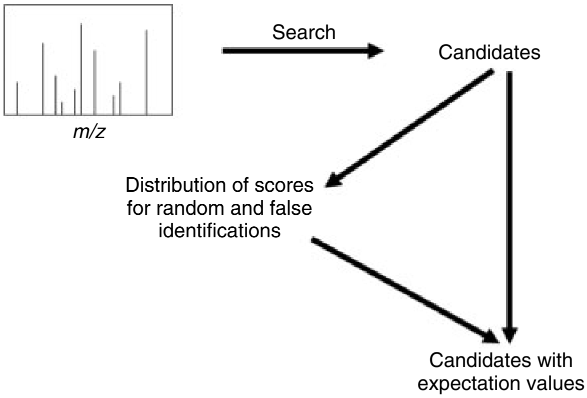

Figure 3 Most protein candidates given by a search engine are due to random matching. The distribution of scores for random and false identifications can therefore be obtained and used to calculate the expectation value for the protein candidates

measured proteolytic peptide masses. The probability that a protein candidate is a false-positive can be estimated by comparing its scores to the distribution of scores for random and false identifications. The distribution of scores for random and false identifications can be obtained by collecting statistics during the search. Figure 3 illustrates the method for using the statistics collected during the search to estimate the significance of the results. A score is calculated for each protein sequence in the collection. For the majority of sequences, the matching with the experimental data is random. An example of the distribution of the scores for proteins in a sequence collection matching a peptide mass fingerprint is shown in Figure 4. Typically, a distribution of scores from randomly matching protein sequences is observed at low scores. This distribution is an extreme value distribution, having a linear tail when plotted on a log–log scale. The expectation value of high-scoring protein sequences is estimated by extrapolation.

3. Search parameters

The different search engines available for peptide mass fingerprinting have a similar set of parameters, including enzyme specificity, sequence collection, modifications, peptide mass tolerance, protein mass, and pI. In cases in which the data quality is very high, a significant result will be obtained with the search parameters set within a wide range. However, in most cases, it is critical to select the parameters carefully when searching a protein sequence collection with peptide mass fingerprinting data. In general, it is recommended that all the information available that can restrict the search be used, for example, if the origin of the sample is known, a lot can be gained by only searching the species of interest and not all known protein sequences from all organisms. Also, information that will increase the number of possible matching peptides in the dataset should be used conservatively, for example, partial modification such as phosphorylation.

It is important to use enzymes with high specificity for peptide mass fingerprinting. The number of incomplete cleavage sites selected will influence the results; a

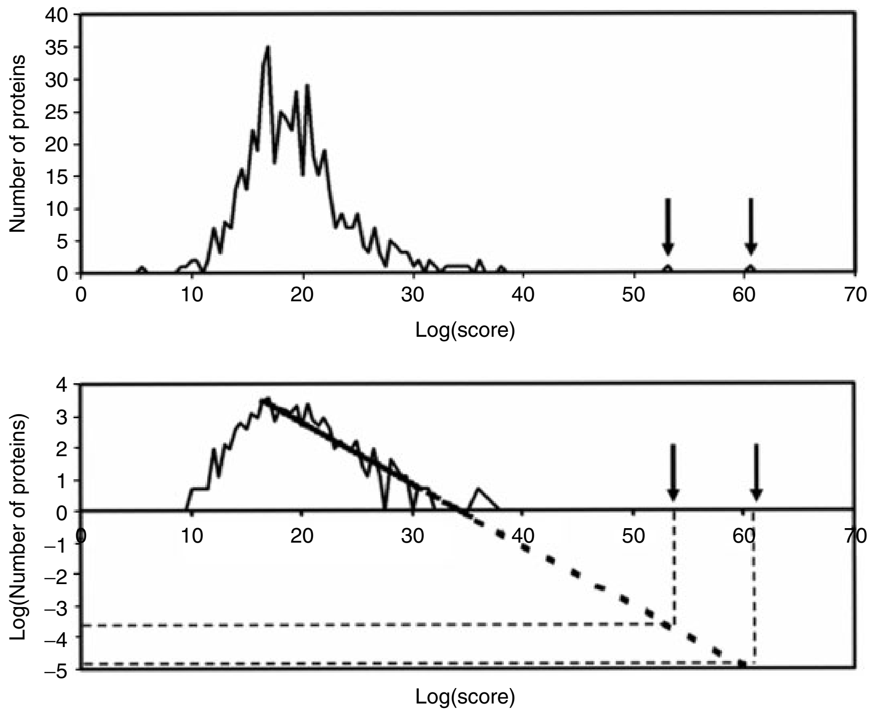

Figure 4 An example of the distribution of scores for random and false identifications for a peptide mass fingerprinting search with ProFound (Zhang and Chait, 2000). The distribution is an extreme value distribution, having a linear tail when plotted on a log–log scale. The expectation value of high-scoring protein sequences is estimated by extrapolation

larger number of incompletes will increase the noise because there will be more possible peptide sequences. This is illustrated in Figure 5 in which the distribution of scores for the random matching shifts to higher scores when the number of possible missed cleavage sites allowed is increased from 1 to 2 and 4. It is therefore recommended that an experimental protocol be used in which the proteins are digested as completely as possible, allowing the search to be performed with a setting of 0 or 1 incomplete cleavage sites.

There are many different sequence collections available for searching. Protein sequence collections are the most common choice for protein identification with peptide mass fingerprinting data. Searching of raw genomic data by translating the entire DNA sequence in all six possible reading frames with peptide mass fingerprinting data can be successful for organisms with small genomes, but is generally not done, because it requires very high quality experimental data. Expressed sequence tag (EST) collections are in general unsuited for searching with peptide mass data, because of their incomplete coverage of the genes. The smaller the sequence collection searched, the higher the significance of the results, provided that the collection contains the sequence of interest (Figure 5), for example, if the origin of the sample is known, it is recommended that only the species of interest be searched.

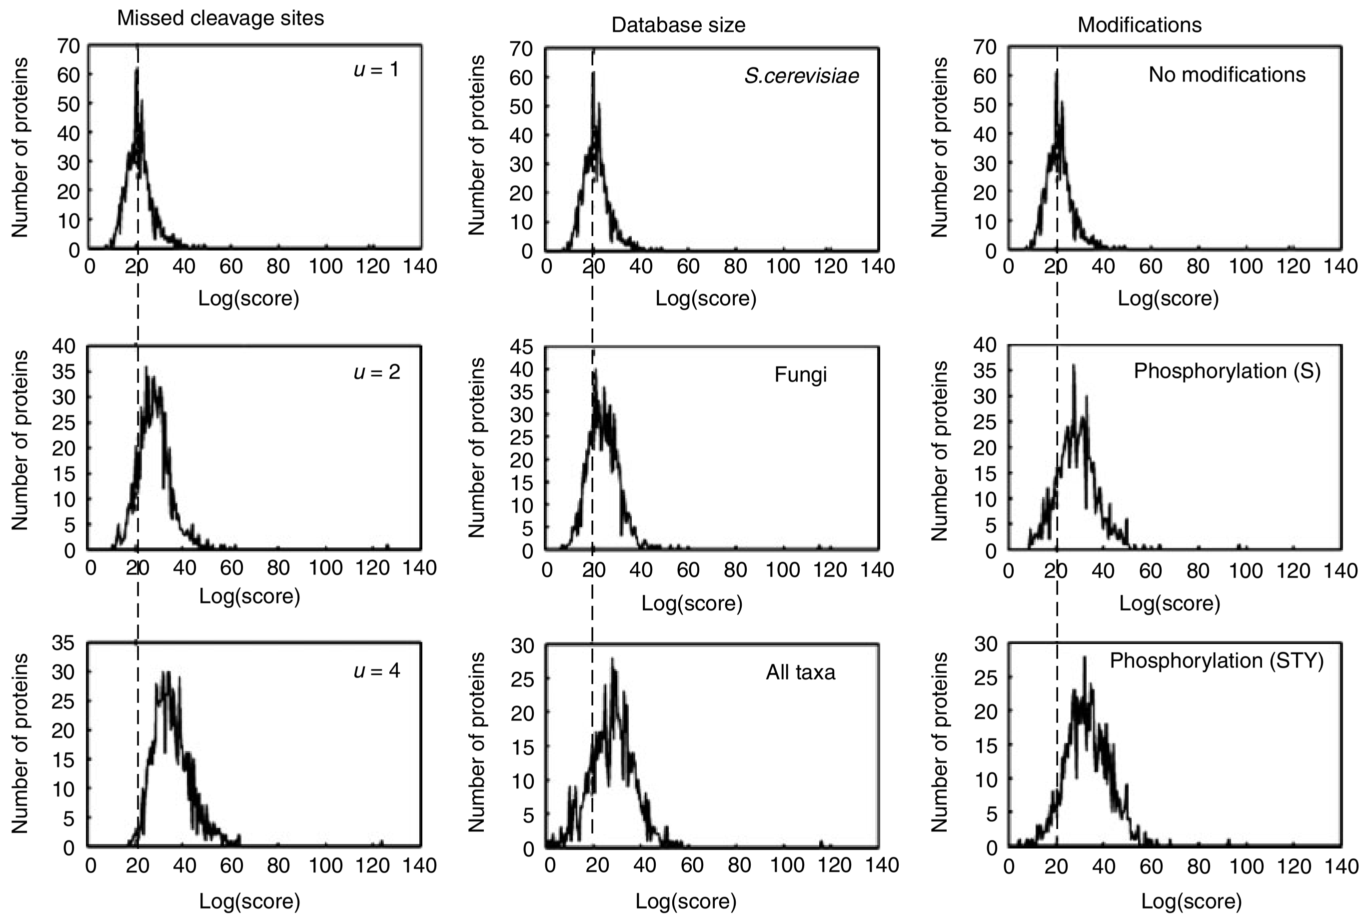

Figure 5 Example showing how the distribution of scores of random matches changes when different parameters are used with the same data set in searches with ProFound (Zhang and Chait, 2000)

Table 1 Example illustrating how the expectation value changes when different parameters (size of sequence collection, missed cleavage sites – *u*, and modifications) are used with the same data set in searches with ProFound (Zhang and Chait, 2000) (See Figure 5)

Sequence collection	E-value	*u*	E-value	Modifications	E-value
S. cerevisiae	4.8E-07	1	4.8E-07	No modifications	4.8E-07
Fungi	8.4E-06	2	1.1E-05	Phosphorylation (S)	2.3E-03
All taxa	2.9E-04	4	6.8E-04	Phosphorylation (STY)	2.1E-02

Proteins are often naturally modified and usually deliberately or unintentionally modified in the sample preparation process. Modifications can be defined as complete (i.e., they are always present on a specific amino acid) or partial (i.e., the modification might or might not be present on an amino acid). Complete modifications (e.g., cystein alkylation) do not increase the search time or change the significance. In contrast, partial modifications (e.g., phosphorylation) increases the search time and in general decreases the significance (Table 1) because the distribution of scores for the random matching shifts to higher scores (see Figure 5). If a peptide contains an amino acid that potentially might be modified, the mass of the unmodified peptide and the masses of the peptide with all possible modifications have to be compared with the measured peptide mass map. Even though a lot of proteins are modified, most proteins have only a few modified amino acids and therefore only a few of the peptides in a peptide mass map will be modified. Searching with partial modifications defined will increase the random background and potentially the number of matching peptides. In most cases, higher significance is achieved when searching without partial modifications defined.

The quality of the results obtained is dependent on the mass tolerance selected (Figure 6). Increasing the mass tolerance will increase the number of both true- and false-matching peptides. The two extreme cases are (1) zero mass tolerance – no peptides match and (2) large mass tolerance – all peptides match. Therefore, the best results are obtained at the mass tolerance that balances the contributions

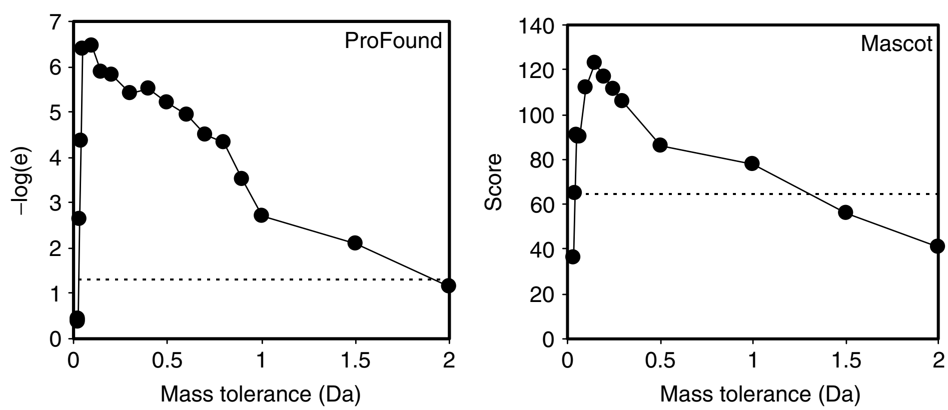

Figure 6 An example showing how the mass tolerance affects the results of the search for ProFound (Zhang and Chait, 2000) and Mascot (Perkins *et al*., 1999). The dotted line shows the probability of 0.05 for the result being false

from true- and false-matching peptides. The best setting for the mass accuracy can differ for different search engines because of the differences in the algorithms, for example, in Figure 6, the best results are obtained with a mass tolerance of 0.15 for Mascot and 0.1 for ProFound.

If the source of the analyte is a spot in 2D gel, information on protein properties such as mass and pI is available. This information can be used to restrict the search by excluding all sequences in the collection being searched that do not match the measured mass and pI and thereby increasing the significance of the results. The tolerance for protein mass and pI should, however, not be set too narrow because the measurement can differ from the calculated because of several reasons: (1) the protein has been processed and only a small domain is observed; (2) the splice variant observed is not in the sequence collection; and (3) the intron–exon boundaries are incorrectly assigned.

4. Summary

For successful protein identification, it is necessary to (1) use a sensitive and selective algorithm; (2) carefully select search parameters; and (3) test the significance of the results. The potential for obtaining a true mass spectrometric protein identification result depends on the choice of algorithm as well as on experimental factors that influence the information content in the mass spectrometric data. Current methods can never definitely prove that a result is true, but an appropriate choice of algorithm can provide a measure of the statistical risk that a result is false – that is, the statistical significance – and guide the practitioner in interpreting the results.

Multidimensional liquid chromatography tandem mass spectrometry for biological discovery

Claire M. Delahunty and John R. Yates III
The Scripps Research Institute, LaJolla, CA, USA

1. Introduction

The goal of biological studies is to connect genes and proteins to specific processes. In the past, dissection of biological processes entailed detailed and focused studies of a specific gene or protein. The availability of complete genome sequences has made possible broader studies to dissect the functions of proteins and genes in entire pathways, thus extending the knowledge of the process. Proteomics in an organism is facilitated by the existence of a completed genome sequence, which allows more facile and higher-throughput correlations between gene and protein sequences than has been possible with more traditional protein-sequencing methods. Correlations are derived through the use of mass spectrometry data that reveals the identity of a protein through the molecular weights of peptides in a tryptic map or by fragment ions of individual peptides. Fragmentation of individual peptides is accomplished through the use of tandem mass spectrometers that can select individual ions, induce dissociation, and record the resulting product ions (Hunt *et al*., 1986). The resulting fragment ions represent the amino acid sequence of the peptide. Fragmentation patterns can be matched to sequences in a database, thus identifying the protein from which the peptide was derived. An analytical advantage to this method is the ability to measure peptide mixtures derived from proteolytically digested protein mixtures (Figure 1) (Yates, 1998). This approach represents an efficient and sensitive method to identify the components of protein complexes, protein localization (e.g., proteins located in organelles or subcellular spaces, cellular membranes), and protein modifications (Link *et al*., 1997; Wu *et al*., 2003).

To accommodate complex protein mixtures, separation systems of high resolution are desirable. Multidimensional liquid chromatography (MudPIT) provides high-resolution separations of peptides in an automated, convenient manner. Link *et al*. (1999) developed an integrated form of MudPIT that combines strong cation exchange (SCX) resin with a reversed-phase (RP) to create a biphasic column

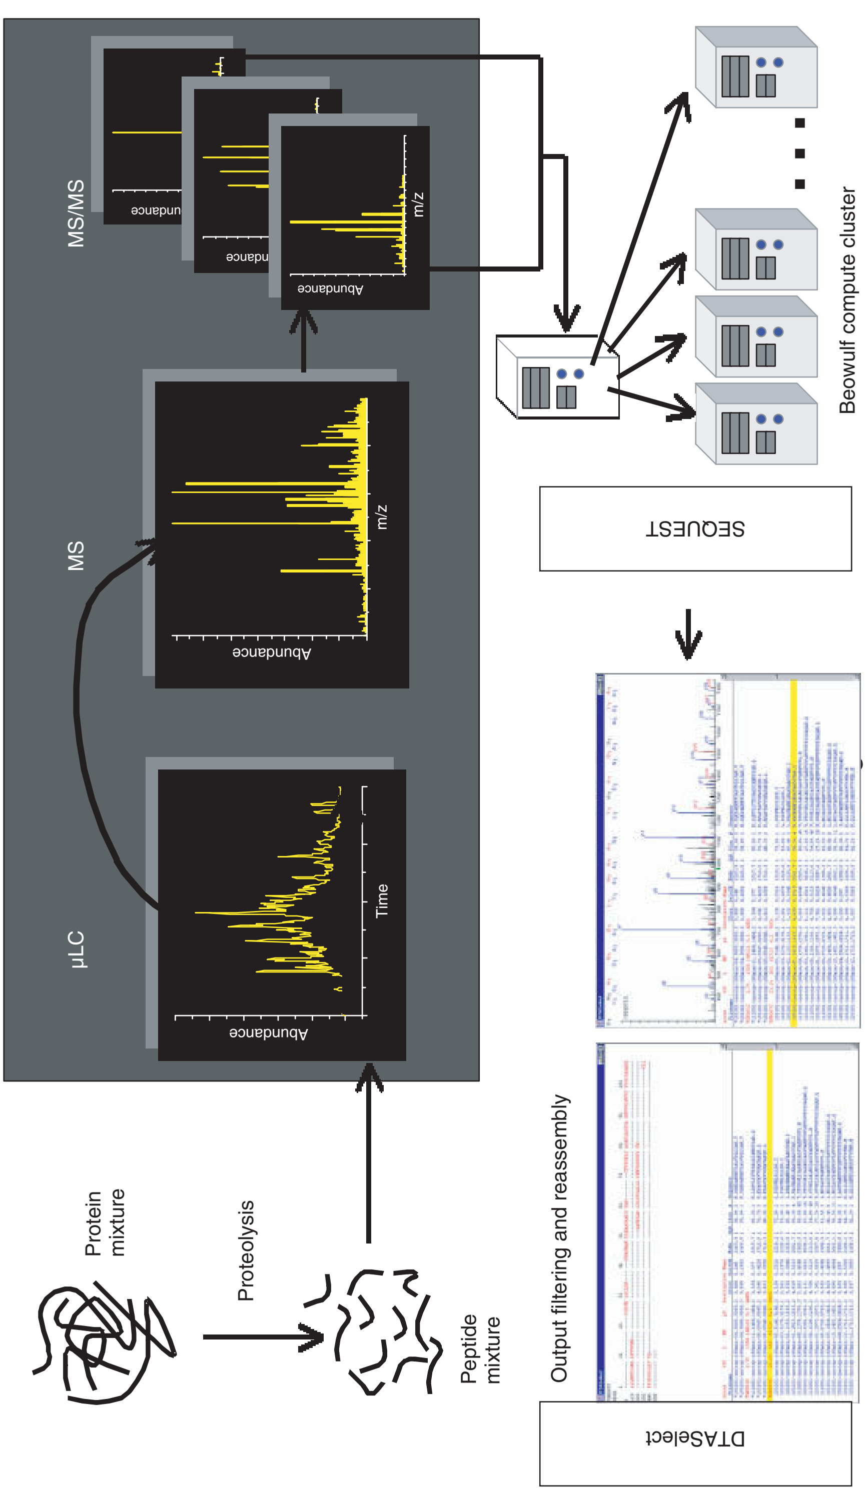

Figure 1 The process of shotgun proteomics involves digesting a protein mixture and then separating the peptides into a tandem mass spectrometer. Peptide ions are individually selected for collision-induced dissociation and then each resulting spectrum is searched through a sequence database. The results are filtered, assembled, and organized to view the results

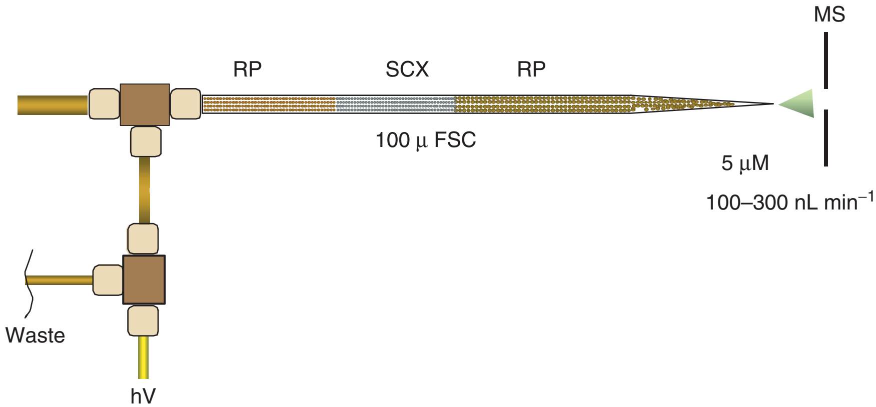

Figure 2 An integrated multidimensional liquid chromatography column to perform high-resolution separations of peptides. The tip of the column is packed with reversed-phase (RP) packing material followed by a layer of strong cation exchange (SCX) resin and then a short layer of RP material. Peptides are electrosprayed out the end of the column directly into a mass spectrometer

(Figure 2). The combination of SCX and RP packing materials creates a bimodal, orthogonal separation by charge and hydrophobicity. Modification to this process was introduced by McDonald *et al*. (2002) to add a third layer of chromatography material to effect an on-column removal of buffer salts that may be present in the sample and to improve retention of peptides on the SCX phase. Washburn *et al*. (2001) demonstrated that this approach was effective for an unbiased analysis of the components of yeast cells by identifying large and small proteins, basic and acidic proteins, and membrane proteins.

2. Analysis of protein complexes

This strategy has been used to improve the analysis of protein complexes and to localize proteins (Figure 3). A recent study used biochemical purification of protein complexes combined with identification using the MudPIT approach (Hazbun *et al*., 2003). The essential hypothetical open reading frames were all epitope-tagged with the Tandem Affinity Purification (TAP) tag that combines a protein A IgG binding domain with the calmodulin-binding peptide (Rigaut *et al*., 1999). The two binding domains are linked together with a short amino acid sequencing containing the tobacco etch virus protease cleavage site. Inclusion of the cleavage site allows protein complexes to be removed from the initial purification step on an IgG column by proteolytic cleavage. The complex is recovered by passing the eluate through a calmodulin column and then released by elution with EDTA (ethylenediamine tetraacetic acid) (Gavin *et al*., 2002). The complex is then digested using trypsin to produce a collection of peptides. Peptides are loaded onto a two-dimensional LC column and separated directly into a tandem mass spectrometer. Tandem mass spectra were automatically collected and then searched against the yeast

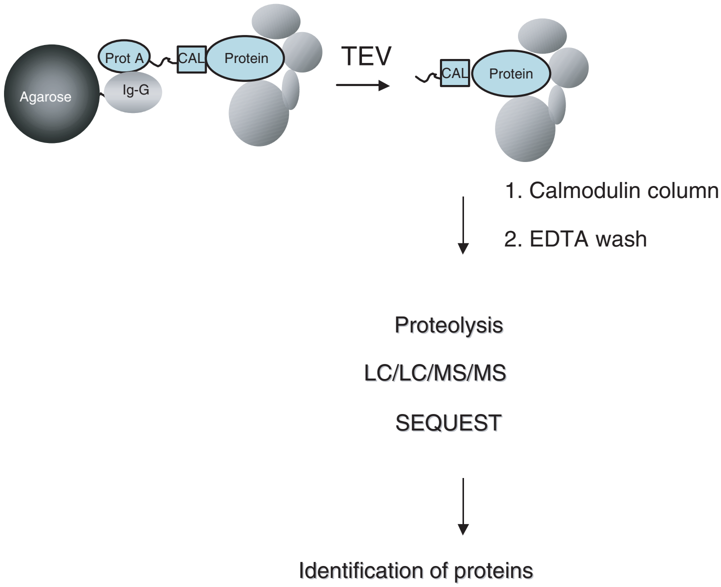

Figure 3 Protein complexes can be analyzed by incorporating an epitope into a protein sequence that contains protein A, the tobacco etch virus protease cleavage site, and the calmodulin-binding peptide. After elution of the complex from the columns, the proteins are digested and analyzed by MudPIT

sequence database to identify the proteins in the mixture. Of the 100 tagged proteins analyzed, complexes were identified for 29 of them. On the basis of the identities of the proteins interacting with the tagged proteins in combination with data from colocalization and yeast two-hybrid experiments, gene ontology annotations could be assigned to the proteins. This study and others have shown MudPIT to be a very effective method to identify proteins in complexes (Graumann *et al*., 2003) as well as to identify sites of modifications in proteins of complexes (Cheeseman *et al*., 2002; MacCoss *et al*., 2002).

3. Analysis of subcellular compartments

A particular challenge for proteomics studies is the identification of proteins in membranes and organelles. These studies are complicated because it is difficult to enrich for membrane or organelle proteins without contamination and because these proteins have limited solubility in buffers compatible with mass spectrometry. By using MudPIT, subtractive analysis approaches can be utilized as well as strategies to digest only the soluble segments of membrane proteins.

Schirmer *et al*. (2003) used a subtractive approach to identify proteins of the nuclear envelope (NE) (Figure 4). Enrichment of the NE is particularly challenging because it is contiguous with the endoplasmic reticulum (ER) and intermixed with mitochondria. An enriched fraction of the microsomal membranes (MM) that includes both ER and mitochondria can be generated. Schirmer *et al*. generated

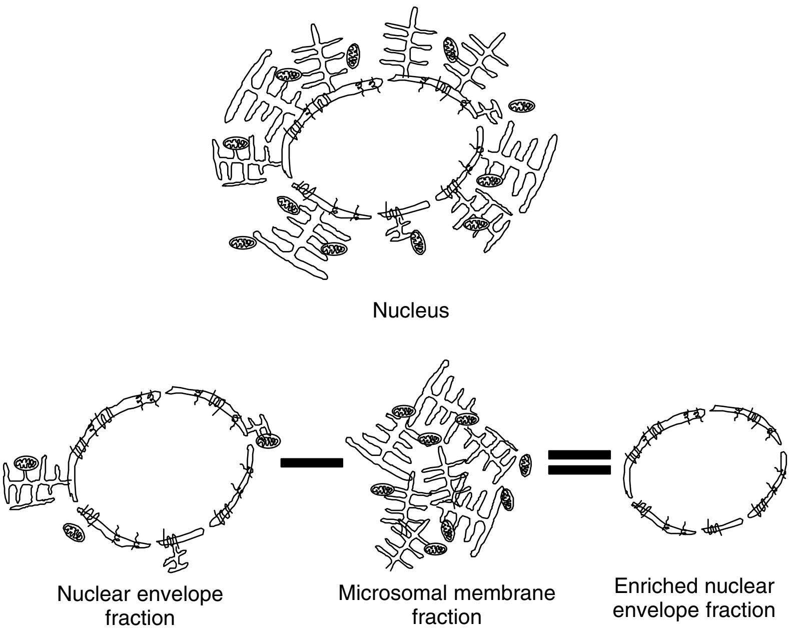

Figure 4 Subtractive proteomics was applied to the nuclear envelope of mammalian cells by enrichment of the microsomal membrane fraction for exhaustive proteome analysis. An enriched nuclear envelope fraction was then analyzed and proteins in common between the two were subtracted from the list of identified proteins

an exhaustive proteome analysis of the microsomal fraction and an enriched NE fraction using MudPIT. Proteins identified in the MM fraction were then subtracted from those identified in the NE fraction. Sixty-seven proteins were identified as hypothetical, integral membrane proteins. This example illustrates a powerful aspect of the shotgun proteomics method enabled by MudPIT. Membrane proteins were readily identified using this approach, since it is not necessary that the proteins be solubilized for digestion only that digestion of the soluble portions of the membrane proteins is achieved. A possible limitation of the approach is potential loss of information from those membrane proteins with minimal regions exposed.

Sample preparation for MALDI and electrospray

J. I. Langridge and M. Snel
Micromass UK Ltd, Manchester, UK

1. Introduction

The development of electrospray (ESI) and matrix-assisted laser desorption/ ionization (MALDI) in the early 1990s built upon the advances made by fast atom bombardment (FAB). FAB allowed the analysis of biomolecules previously intractable to mass spectrometric analysis, without derivatization. The subsequent development of MALDI and ESI provided increased sensitivity while significantly increasing the molecular mass of proteins that could be accurately measured. Further refinement of both ionization techniques and the associated mass analyzers has provided modern, state-of-the-art instrumentation that can detect low levels of endogenous biological samples with high accuracy. In particular, the coupling of MALDI and ESI with mass spectrometers capable of MS/MS (*see* Article 10, **Hybrid MS**, Volume 5) has resulted in significant advances in protein identification and characterization. However, one of the limiting factors in this inherently sensitive technology is the preparation of samples for the mass spectrometer. This crucial step often defines the quality of results obtained. For example, one common cause of problems is the incomplete removal of buffers used in the biology laboratory. The presence of detergents, salts, and other common buffer components can adversely affect the performance of ESI and MALDI mass spectrometers. The presence of alkali metals in a sample can cause what should be a single component to appear as multiple adduct peaks containing varying numbers of metal ions.

The following section details the most commonly used sample preparation techniques in use in the laboratory today.

2. Sample preparation for MALDI

Matrix-assisted laser desorption/ionization is a soft ionization technique. In this technique, the analyte molecules are embedded in a matrix consisting of small organic molecules. The sample is irradiated with a laser pulse, which leads to rapid heating of the matrix molecules and results in a transition into the gas phase. Analyte molecules included in the matrix are also brought into the gas phase and are ionized, often through adduct formation. In its ionized form, the analyte can be separated according to its m/z ratio, using a variety of different mass analyzers.

In modern configurations, a time-of-flight (TOF) mass analyzer (*see* Article 7, **Time-of-flight mass spectrometry**, Volume 5) is most commonly used.

MALDI sample preparation of peptide and protein samples can be extremely straightforward, and as a result, MALDI has rapidly established itself as one of the standard techniques for rapid protein identification. In the years after the introduction of MALDI, the main focus was on the mass determination of intact proteins. The emphasis shifted rapidly to peptide analysis, with the invention of a new technique for protein identification termed *peptide mass fingerprinting* (*PMF*) (*see* Article 3, **Tandem mass spectrometry database searching**, Volume 5). In this approach, proteins are enzymatically digested, typically with trypsin, and the resultant peptides mass-measured. The monoisotopic masses obtained from the MALDI PMF experiment are then compared to a protein or nucleotide sequence database. The main sample preparation factors affecting the overall performance of MALDI experiments are choice of matrix, sample purity, solvents used, and the method of applying the matrix and sample. More specialized applications such as phosphopeptide analysis may require more rigorous sample cleanup and sample preparation routines, and these are dealt with later under electrospray sample preparation.

2.1. Sample cleanup

The best results in MALDI analysis are obtained from clean samples. Much can be done in the steps leading up to the MALDI analysis to reduce or even eliminate the need for sample cleanup. Common biological buffers, contaminants, and salts can be tolerated to the levels shown in Table 1. If the buffer/salt levels are too high, these can be reduced by a number of different methods. A widely used technique is binding peptides on reverse-phase material and then washing them with aqueous solutions, followed by elution in high organic. Alternatively, salts may be removed by dialysis. Washing of the sample by adding a droplet of water to a prepared MALDI sample spot and then drawing off the liquid and salt has also been shown to be a useful strategy. It should, however, always be borne in mind that sample cleaning may result in some loss or dilution of sample and if it can be avoided through careful choice of the sample preparation steps, then the best results will be obtained. A common source of sample contamination when a protein sample is being enzymatically digested is keratin. This originates from clothing and human skin, and it is often surprising to researchers when they first start working with MALDI just how sensitive the technique is and how readily keratin can be detected. This contamination can usually be avoided through the use of gloves and clean air enclosures.

2.2. Choice of matrix and solvent

There are numerous ways to prepare a given sample for analysis by MALDI, however, some broad guidelines can be made. The first choice that needs to

Table 1 Common buffers and contaminants and the maximum concentrations tolerated in MALDI and ESI MS

Contaminant	MALDI max. conc.	ESI max. conc.
Phosphate buffer	20 mM	<2 mM
Tris buffer	50 mM	5 mM
Detergents	0.1%	0.1%
SDS	0.01%	0.01%
Alkali metal salts	1 M	–
Glycerol	2%	–
NH_4 bicarbonate	30 mM	50 mM
Guanidine	1 M	10 mM
Sodium azide	1%	–

be made is the choice of matrix. Over the years, a large number of matrices have been suggested, however, two have been used routinely for the analysis of peptides. The most commonly used matrix for peptide mass fingerprinting is α-cyano-4-hydroxycinnamic acid (CHCA). It is relatively easy to obtain fine matrix crystals with this matrix, which tends to give a more homogenous sample surface. A homogenous sample surface makes it easier to find a "hot spot" providing mass spectra containing the analyte of interest. It is also possible to get excellent sensitivity with this matrix. Several different concentration levels and solvents have been suggested for the preparation of CHCA, however, the most commonly used concentration is 10 mg mL^{-1}. Despite this, experiments have shown that for low peptide concentrations, that is, subpicomol on target, matrix concentrations of 2 mg mL^{-1} or lower work better. The solvent mix used depends on the evaporation rate desired; this can be very dependent on ambient humidity and temperature. A mixture of 1:1 acetonitrile:water containing 0.1% trifluoroacetic acid (TFA) generally works well, although the water can also be replaced by ethanol.

For protein analysis, sinapinic acid can be a very effective matrix. This matrix can be used in a dried droplet experiment and in thin-film preparations (see spotting methods). For both of these methods, a sinapinic acid solution of 10 mg mL^{-1} in 6:4 acetonitrile:0.1% TFA is used. The thin-film method additionally calls for a sinapinic acid solution of 10 mg mL^{-1} in acetone or acetonitrile. Sinapinic acid forms very homogenous sample spots with an even analyte distribution.

Another versatile matrix is 2,5-dihydroxybenzoic acid (DHB). This can be used for protein and peptide analysis but is also the matrix of choice for other compounds, for example, oligosaccharides. DHB tends to form large crystals, where the analyte is not evenly distributed and this leads to localized hot spots usually at the tips and edges of the crystals. A wide range of different solvent mixtures and matrix concentrations has been suggested for DHB. A typical example would be 20 mg mL^{-1} in 7:3 0.1% TFA:acetonitrile. Several other matrices and various derivations of the above matrices have also been described in the literature but these are not widely used.

2.3. Spotting methods

Several different spotting methods have been developed for MALDI samples. The methods mostly differ in the way the matrix solution is combined with the analyte solution, and they can have a drastic effect on the quality of the MALDI mass spectrum acquired.

The dried droplet method is a reliable and straightforward method. Roughly equal volumes of matrix and sample solution are mixed. This can be done prior to spotting in the sample tube, followed by spotting of a 00.5–2 μL droplet onto the target plate. This droplet is then allowed to dry either under normal lab conditions or at slightly reduced pressure. Alternatively, the matrix and analyte solutions can be combined directly on the target plate by first depositing a small volume of matrix (0.5–2 μL) and then subsequently adding a droplet of analyte solution. Mixing can then either be left to diffusion or can be aided by aspiration of the matrix/analyte droplet on the target plate using a pipette. Contact of the pipette tip with the sample holder should be avoided, as this can cause crystallization of the matrix.

The sandwich and thin-film methods are slightly more involved in comparison to the dried droplet method. However, these methods can be particularly effective for protein analysis, on-target desalting, and high-sensitivity work. In these methods, a thin film of matrix is deposited on the target plate and allowed to dry. Depositing a small volume of matrix in high organic, for example, acetone, produces the thin film. This thin film consists of very fine crystals. The sample solution added, either combined with matrix or on its own, and the solvent mix in the droplet that is added must be in a high aqueous environment to avoid dissolving the thin film.

A further derivation of this technique is the sandwich method in which a drop of matrix solution is applied after this procedure, covering the analyte with a matrix layer.

3. Sample preparation for electrospray

Electrospray ionization is a soft ionization technique. The sample is introduced into the electrospray ion source as a continuous liquid stream. As such, ESI is often directly coupled to on-line sample cleanup and separation techniques, such as liquid chromatography. This forms the basis of most sample preparation techniques for ESI. LC-ESI MS is compatible with a wide range of solvent compositions and ionizes a diverse range of compounds. It has found particular use in the area of biological mass spectrometry due to the ability of molecular species to accept multiple charges during the electrospray process. As the mass spectrometer separates according to mass/charge (m/z), high-molecular-weight compounds, such as large protein complexes, now appear lower down the m/z range, within the mass range of conventional mass analyzers.

Further refinements of electrospray for biological applications resulted in the development of nanoelectrospray (Wilm and Mann, 1994), where flow rates of the liquid stream maybe as low as a few nanoliters per minute. One of the limiting factors for analysis of proteins and peptides by electrospray or nanoelectrospray

mass spectrometry is sample preparation. The presence of many biological buffers (e.g., HEPES, Urea) interfere with the ionization process and as such they should be avoided, or removed, prior to analysis.

3.1. Purification and concentration by reverse phase

A common strategy in the analysis of protein and peptide samples by mass spectrometry is to improve the quality of the data acquired by using reversed phase (RP) chromatography. This approach allows peptides or proteins to be separated on the basis of their hydrophobicity, and is often used "on-line", coupling liquid chromatography directly to an electrospray MS instrument. This approach has been used widely for the analysis of oligonucleotides, intact proteins, and proteolytic digests of proteins. The RP HPLC separation requires an ion-pairing reagent, and with traditional protein and peptide separation, 0.1–1% trifluoroacetic acid (TFA) is used. The sensitivity of ESI ionization is reduced by approximately a factor of 5 if TFA is present in the liquid stream, and as such alternative stationary phases have been produced by a variety of manufacturers that provide excellent separations using 0.1–1% formic acid as the ion pair. This provides an increase in ESI sensitivity compared to the TFA-based separation. In addition, as ESI is a concentration-dependent ionization technique, the use of capillary and nanoscale chromatography has lead to significant advances in ESI sensitivity.

For peptide analysis, the HPLC is often coupled to a mass spectrometer capable of data-directed switching between the MS and MS/MS modes. Hundreds of MS/MS spectra can be acquired from complex peptide samples in a fully automated fashion, resulting in the structural characterization of many species in a single analysis. For example, protein identification can be achieved via data bank searching of the ESI-MS/MS, providing qualitative information on the proteins that are present and identification of significant numbers of proteins, including low copy number proteins, from a single LC-MS/MS experiment.

The use of microcolumns for ESI sample preparation of in-gel digested samples for nano-ESI was first described by Wilm and Mann (1996). A small amount of reverse-phase material was packed into the tip of a nanospray needle and used only once, a new column being made for each sample. This provides a crude separation using step elution to desalt and concentrate analytes prior to analysis, and this approach has been shown to provide impressive levels of sensitivity. While this approach was first described for ESI, it has also been widely adopted for MALDI (Gobom *et al*., 1999). Disposable pipette tips packed with reverse-phase material have become commercially available from numerous sources and are suited to robotic sample preparation.

3.2. Strong cation exchange (SCX)

If a complex peptide or protein mixture is to be investigated, then a fractionation step prior to analysis via ESI RPLC-MS is advantageous. The use of SCX material provides an orthogonal separation mechanism to RP, separating peptides

or proteins, on the basis of their inherent or carried charge. It is therefore possible to prefractionate the peptides, prior to further separation by reverse-phase on a C18 column. This provides additional separation power, or peak capacity. A further derivation of this approach has seen the use of a biphasic column, where both SCX and RP material are sequentially packed into a nanoscale HPLC column. This allows two-dimensional LC separations to be performed on-line to the mass spectrometer (Link *et al*., 1999).

3.3. Hydrophilic interaction liquid chromatography (HILIC)

HILIC is a versatile, effective alternative to ion exchange and reverse-phase chromatography for the increased retention and separation of polar peptides. The technique permits direct coupling via LC-MS. An additional advantage of HILIC is that it works best where RP works worst – with polar solutes that are poorly retained on RP material. HILIC has been used successfully for the analysis of phosphopeptides, carbohydrates, peptide digests, and polar lipids.

HILIC separates compounds by eluting mostly organic mobile phase over a neutral hydrophilic stationary phase. This results in solutes eluting in order of increasing hydrophilicity – the inverse of reverse phase.

3.4. Purification using graphite columns

The use of reverse-phase material to desalt and concentrate proteolytic digests prior to mass spectrometry is widespread, as discussed previously. However, this does not allow for detection of small or hydrophilic peptides, or peptides altered in hydrophilicity. The use of graphite powder, in a microcolumn format, allows hydrophilic species to be retained efficiently on the graphite (Larsen *et al*., 2002). These can then be eluted and analyzed by mass spectrometry.

3.5. Immobilized metal-affinity chromatography (IMAC)

Despite the ability of mass spectrometry to analyze peptide components in complex mixtures, the detection of endogenous levels of phosphopeptides in a peptide mixture can be problematical. This is partly due to the low ionization efficiency of the phosphorylated species, and also due to the low stoichiometry of phosphorylation. Analysis of phosphorylation sites in complex mixtures can be facilitated through the use of affinity methods, which isolate and enrich phosphopeptides from samples prior to mass spectrometry. A popular method for isolating and enriching involves using trivalent metal ions, such as Fe^{3+}, Ga^{3+}, or Ni^{3+} that are bound to a chromatographic support. This technique is referred to as immobilized metal-affinity chromatography (IMAC). Primarily, IMAC experiments are performed in an off-line manner, with microcolumns (Stensballe *et al*., 2001), although on-line studies have also been reported.

1. Introduction

In spite of their vital importance to many cellular functions, we remain remarkably ignorant of membrane protein composition. Two major classes of membrane proteins exist: integral membrane proteins, which are embedded in the lipid bilayer, and the so-called peripheral membrane proteins, which are associated noncovalently with integral proteins or membrane lipid head groups (Figure 1).

Membrane protein structural biology lags behind that of the more-soluble class of proteins because only 0.2% of the ~17 000 known protein structures are integral membrane proteins. This is in contrast to a detailed bioinformatic analysis of integral membrane proteins of the helix-bundle class by Wallin and von Heijne (1998), which predicts that 20 to 30% of all open reading frames encode membrane proteins. Integral membrane proteins are also grossly underrepresented in proteomic analyses. These shortcomings have occurred because of the enormous technical challenges associated with their handling and characteristics. Such challenges arise from the low relative abundance of membrane proteins, insolubility caused by the hydrophobicity of their lipid embedded portions, and the variability of their posttranslational modifications, particularly glycosylation.

2. Membrane enrichment

Two-dimensional electrophoretic (2DE) gels are the classical proteomic tool for separation and visualization of complex protein samples (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5 and Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5); however, the low relative abundance of integral

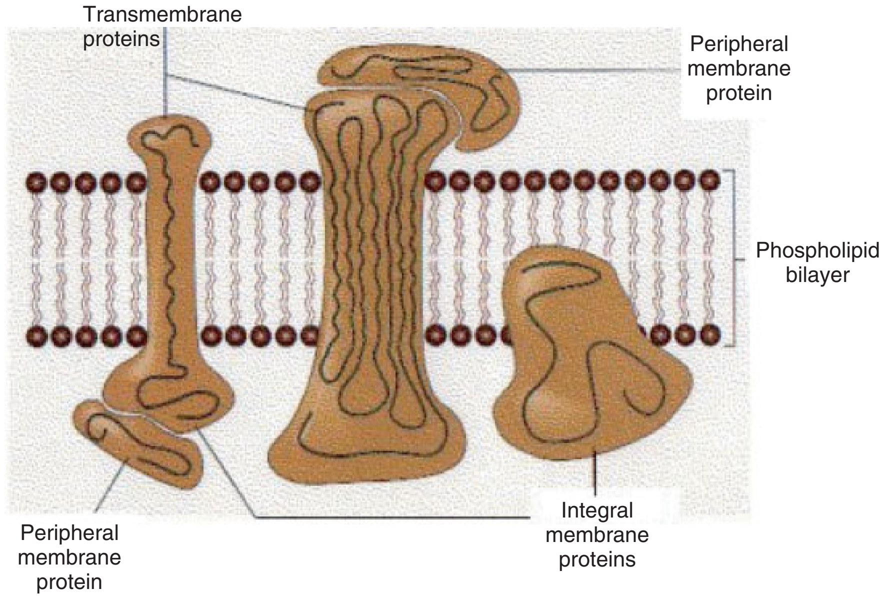

Figure 1 Diagrammatic representation of membrane protein structure. Integral membrane proteins are embedded in the lipid bilayer, while peripheral membrane proteins can be associated with other membrane proteins or with lipid head groups (not shown). (©2004 John W. Kimball. Reproduced by permission of John W. Kimball)

membrane proteins (compared with abundant cytoskeletal, cytoplasmic, and vesicle lumen proteins) makes their detection on 2DE gels near impossible owing to the dynamic range of most visualization methods (around 3–4 orders of magnitude). Therefore, various enrichment strategies have been performed prior to their analysis and identification (for reviews see Thomas and McNamee, 1990; Celis, 1998).

The simplest enrichment method is a microsomal preparation, in which ultracentrifugation is used to pellet the dense cellular membranes after mechanical cell lysis and removal of nuclei and unlysed cells (Simpson, Connolly *et al*., 2000). An advancement of this technique is the use of density gradients to fractionate the various cellular membranes according to their different densities (Pasquali, Fialka *et al*., 1999; Adam, Boyd *et al*., 2003). Sucrose was traditionally used to form the density gradients, although, more recently, Percoll or OptiPrep™ (Iodixanol) have been substituted in order to form nearly iso-osmotic gradients (Ford *et al*., 1994; Pertoft, 2000). Although it is claimed that these methods yield plasma membranes that are free of whole cells, nuclei, and soluble proteins (Thomas and McNamee, 1990), experience suggests that such preparations from epithelial cell lines are heavily contaminated with abundant soluble proteins, such as chaperones, histones, and ribosomal proteins, as judged by detailed mass spectrometry (MS) analysis (Simpson, Connolly *et al*., 2000; Adam, Boyd *et al*., 2003).

Several alternate methods exist for specifically enriching the plasma membrane, including in situ labeling with either a dense bead (e.g., cationic colloidal silica method (Chaney and Jacobson, 1983; Rahbar and Fenselau, 2004)) or an affinity tag

for its subsequent purification on an affinity matrix (e.g., cell surface biotinylation and streptavidin purification (Altin and Pagler, 1995; Shin, Wang *et al*., 2003; Peirce, Wait *et al*., 2004)).

Whilst still embedded in the lipid bilayer, integral membrane proteins can be further enriched by removing many peripheral membrane proteins and nonspecifically bound proteins by washing the membrane pellet with a variety of buffers that interrupt interactions dependent on metal ions (e.g., chelators, EDTA/EGTA) or ionic interactions (e.g., high salt concentrations or high pH buffers, such as 1 M NaCl or sodium carbonate (pH 11), respectively) (Thomas and McNamee, 1990).

3. Solubilization and separation

Solubilization of integral membrane proteins is essential for their subsequent fractionation and characterization, with detergents being the most commonly used method. Although very effective for solubilizing integral membrane proteins, ionic detergents such as sodium dodecyl sulfate (SDS), interfere with isoelectric focusing, the first dimension of 2DE, as well as mass spectrometry. Therefore, other zwitterionic detergents have been tested for both their ability to solubilize integral membrane proteins and their compatibility with 2DE (Henningsen, Gale *et al*., 2002; Luche, Santoni *et al*., 2003; Tastet, Charmont *et al*., 2003; Taylor and Pfeiffer, 2003). However, as no detergent solubilizes all proteins in 2D gels, several other gel-based techniques are available that offer higher solubility at the cost of lower resolving power, such as various one-dimensional PAGE techniques (Simpson, 2003), or the two-dimensional BAC-PAGE (Macfarlane, 1983; Hartinger, Stenius *et al*., 1996) and dSDS-PAGE (Rais, Karas *et al*., 2004).

Chromatographic separation of membrane proteins has been troublesome due to their hydrophobicity, insolubility, and the incompatibility of several chromatographic media with detergents. One exception is hydroxyapatite, which has been used successfully with both ionic and nonionic detergents for membrane protein purification (Fonyo, 1968; Riccio, Aquila *et al*., 1975; Engel, Schagger *et al*., 1980; Valpuesta and Barbon, 1988; Lundahl, Watanabe *et al*., 1992) and as a detergent exchange step prior to 2DE (Wissing, Heim *et al*., 2000). Alternatively, multidimensional liquid chromatography (MDLC), which combines strong cation exchange and reverse-phase liquid chromatography, interfaced with MS has been used to resolve and identify soluble tryptic peptides from membrane proteins (Washburn, Wolters *et al*., 2001). Mass spectrometry is generally impeded by the presence of detergents; however, recently acid-labile surfactants have been shown to improve the recovery of membrane protein–derived peptides in MS analyses (Norris, Porter *et al*., 2003; Yu, Gilar *et al*., 2004) and even positively select for membrane-spanning peptides (Yu, Gilar *et al*., 2004).

4. Dealing with glycosylation

Finally, over 70% of extracellularly exposed proteins are predicted to harbor carbohydrate modifications, which can be highly heterogeneous in composition (Gahmberg and Tolvanen, 1996). This reduces their resolution during separation at both

the protein and peptide level. Therefore, deglycosylation methods have been used to remove carbohydrate moieties either selectively using various enzymes (most commonly PNGase F (EC 3.5.1.52)) or indiscriminately using trifluoromethanesulfonic acid (CAS# 1493-13-6), with the latter being far more efficient (Fryksdale, Jedrzejewski *et al*., 2002).

Improvement of sequence coverage in peptide mass fingerprinting

Karin Hjernø and Peter Roepstorff
University of Southern Denmark, Odense, Denmark

1. Introduction

Detailed information regarding the presence of isoforms, splice variants, and posttranslational modifications (PTMs) is essential for the complete understanding of the biological function, location, and properties of a specific protein.

Traditionally, proteomic studies are based on protein separation using two-dimensional (2D) gel electrophoresis followed by identification by mass spectrometry (MS). An alternative strategy based on separation of peptides derived by enzymatic digestion of complex protein mixture using 2D liquid chromatography systems coupled to mass spectrometry has gained extensive use because it allows automation and high throughput. In this approach, each protein is identified on the basis of only a few peptides. However, studies of different isoforms and changes in protein modification require high coverage of the protein sequence and are still best performed after separation of the proteins for example by 2D gels.

Several strategies have been developed for the specific detection of PTMs such as phosphorylation, nitrosylation, glycosylation, and acetylation (Mann and Jensen, 2003; *see also* Article 61, **Posttranslational modification of proteins**, Volume 6). Most of these are designed to identify one specific type of modification by selective enrichment of the modified peptides (for review, see Jensen, 2004).

However, if the aim is to fully characterize a protein and its modifications, a more global strategy for full characterization of proteins is needed. This requires that signals covering all or the majority of the protein sequence are observed, that is, a high sequence coverage is obtained. Although sequence coverage close to 100% might be obtained in peptide mass fingerprinting by Matrix Assisted Laser Desorption/Ionization (MALDI) MS, protein identification is often performed with sequence coverage as low as 10%, and essential peptides may fail to be identified for different reasons. The main cause is selective ion suppression during the mass spectrometric analysis of the complex peptide mixtures. Additional reasons for low sequence coverage are loss of peptides during sample handling and the fact that modified peptides often have a low stochiometri. Consequently, the normal fingerprint procedure has to be carefully optimized before (if ever) a full characterization of the protein can be obtained.

In the following section, we will discuss strategies useful for enhancing the sequence coverage by using complementary information gained by the use of different enzymes for protein cleavage, different methods for enrichment, different matrices, and/or different ionization methods. The strategies described all assume that the proteins are separated, for example, by 2D-PAGE prior to characterization.

2. Enzymatic digestion

Traditionally, trypsin is the enzyme of choice for protein and peptide mass fingerprinting. The masses of tryptic peptides are typically within the range of 700–2500 Dalton (Da), which is optimal for protein identification by peptide mass fingerprinting. However, digestion with a single enzyme will often not provide complete sequence coverage. This is partly due to generation of a number of too large or too small peptides that may not be detected under the chosen conditions.

Especially, lysine-terminated peptides with masses below 1000 Da will often be lost in purification procedure or missing in the spectra owing to suppression effects (see below). However, by using suboptimal digestion conditions, these peptides might be observed as part of larger peptides containing one or more missed cleavage sites.

A more efficient strategy to increase sequence coverage is to combine data from the tryptic digestion with those obtained by digestion with proteolytic enzymes with different specificity. Several examples of successful improvement of the sequence coverage using multiple enzymatic digests are given in the literature (Larsen *et al*., 2001; Choudhary *et al*., 2003; MacCoss *et al*., 2002). Examples of proteases with high specificity are endoproteinases Lys-C, Asp-N, and Glu-C, all of which can be used for in-gel as well as in-solution digestion. The use of specific enzymes can be combined with digestion using less specific enzymes such as subtilisin and chymotrypsin, which generally produce smaller peptides. Inclusion of these enzymes might be an advantage when the specific enzymes produce too large peptides either because of lack of appropriate cleavage sites or because of large modifying groups, which might cause steric hindrance for the enzyme action.

3. Signal suppression effects

Ion suppression is not a fully characterized phenomenon. It is influenced by a combination of presence of impurities, gas-phase affinity of the peptides, choice of matrix in MALDI, and choice of ionization and acquisition method.

3.1. Removal of impurities

The presence of impurities such as salt, buffers, and detergents can result in adducts formation and thereby in reduced signal intensities or can lead to complete suppression of peptide signals. Therefore, desalting/cleanup and concentration of the digest prior to mass spectrometric analysis is crucial, especially when analyzing

low amounts of starting material (e.g., low abundant protein spots). This can be achieved with commercial microcolumns (e.g., ZipTip's from Millipore (Billerica, MA, USA)) or by using small reversed-phase Poros R2 columns made in gel loader tips (Gobom *et al*., 1999). The peptides are bound to the reversed-phase material followed by removal of the contaminants by a washing step and subsequent elution of the peptides directly onto the MALDI target using a matrix solution (Gobom *et al*., 1999).

We have observed that some small hydrophilic and large hydrophobic peptides are lost in this procedure because they are either not retained on the reversed-phase column or not eluted by the matrix solution respectively (Larsen *et al*., 2002; Laugesen and Roepstorff, 2003). The small hydrophilic peptides can be trapped by passing the flow-through from the reverse-phase columns onto a column containing graphite instead of the Poros R2 material, followed again by elution with matrix solution (Larsen *et al*., 2002).

The graphite columns have also been demonstrated to efficiently retain hydrophilic modified peptides such as phosphorylated and glycosylated peptides and thereby improve the chance to identify these modified peptides (Larsen *et al*., 2004).

3.2. Ion suppression/Preferential ionization in MALDI

It is found that tryptic peptides having a C-terminal arginine give higher signal intensity than lysine-terminated peptides, most likely owing to the high proton affinity of the guanidinium group in arginine (Krause *et al*., 1999). Conversion of the lysine residues to the more basic homoarginine by reaction with *O*-methylisourea prior to analysis enhances the signals for lysine-containing peptides, resulting in increased sequence coverage (Brancia *et al*., 2000; Hale *et al*., 2000; Beardsley *et al*., 2000). A recent study by the group of Krause indicates that the presence of phenylalanine, leucine, and proline in the peptide also seems to enhance the desorption/ionization process, resulting in higher signal intensities in a MALDI spectrum, demonstrating that ionization efficiency is a complex and not fully understood phenomenon (Baumgart *et al*., 2004).

3.3. Matrix selection

The choice of matrix also influences the sequence coverage. Thus, different sequence coverages can be obtained when the same digest is analyzed with the three commonly used matrices for peptide/protein fingerprinting: 2,5-dihydroxybenzoic acid (DHB), α-cyano-4-hydroxycinnamic acid (CHCA), and sinapinic acid (SA) (*see* Article 14, **Sample preparation for MALDI and electrospray**, Volume 5). As a consequence, improved sequence coverage can be obtained by combining the results from analysis with different matrices (Gonnet *et al*., 2003; Gobom *et al*., 1999). The use of matrix mixtures has also been reported to increase the sequence coverage compared to the use of a single matrix (Laugesen and Roepstorff, 2003). In addition, these matrix mixtures seem to be more tolerant toward the presence of impurities and thus reduce the need for sample purification.

3.4. Choice of acquisition and ionization method

For a simple protein identification, the MALDI time-of-flight instrument will typically be optimized to yield maximal sensitivity and resolution in the mass range between 700 and 3500 Da, with a highest resolution around 2000 Da. However, by tuning the mass spectrometer (grid voltage and delay time), an improved sensitivity and resolution for the detection of larger peptides at the cost of the smaller can be obtained. Repeated acquisitions with the instrument optimized for different mass regions, therefore, often provide better sequence coverage.

The choice of ionization method also influences which peptides are observed. Thus, our experience, as well as the experience of Kast *et al*. (2003), tells us that only between one-third and one-half of the peptides in a mixture, or even less, are observed in common for Electrospray Ionization (ESI) and MALDI MS. By combining the results from the two ionization methods, nano-ESI and MALDI, considerable improvements of the sequence coverage in protein fingerprinting can be obtained.

3.5. Liquid Chromatography Mass Spectrometry, LCMS

The use of a separation step prior to mass spectrometric analysis overcomes many of the above-mentioned shortcomings when analyzing peptide mixtures. The prepurification step is integrated in the LCMS (Liquid Chromatography Mass Spectrometry) procedure. By separating the individual peptides before reaching the mass spectrometer, suppression effects are reduced or nonexistent and, consequently, sequence coverage close to 100% should be obtainable provided that all the peptides are retained on and subsequently eluted from the chromatographic column, which is not always the case (see above). Until recently, LCMS was only available on ESI instruments. However, off-line LC-MALDI-MS has gained increasing interest, and unpublished data from several groups indicate that this method results in even better sequence coverage than LC-ESI-MS.

4. Interactive data handling

For the description above, it is obvious that complete sequence coverage including observation of peptides present in substochiometric amounts is highly dependent on the complexity of the peptide mixture. Consequently, a prerequisite for complete coverage of the protein sequence including minor variants is that the proteins of interest are isolated prior to analysis (e.g., by 2D gels) and that contaminating proteins such as keratins are eliminated as well as the enzyme used are high quality with minimal autodigestion. Alternatively, exclusion list containing all the masses of known contaminating peptides has to be developed before or during the experiments (using either the program PeakErazor (**http://welcome.to/GPMAW**) or similar software package) to avoid wasting sample material on identifying peptides belonging to contaminants or peptides already identified.

As soon as the protein is identified, interactive data handling needs to be performed. By making an in silico digest of the protein after identification, the nondetected peptides can be examined for their chemical/physical properties such as hydrophobicity/hydrophilicity, acidity/basicity, predicted modifications, and m/z-values. On the basis of this information, a strategy for the detection of these peptides or their potentially modified forms can be designed using the approaches suggested for improving sequence coverage described above.

The interactive data handling can be combined with the concept of hypothesis-driven multistage MS introduced by Kalkum *et al*. (2003) in which they calculate the mass for peptides predicted to be present, but only in trace amounts, for example, possible modified peptides or peptides representing isoforms and splice variants. By performing MS/MS or MS^3 in a MALDI-ion-trap after selecting the appropriate mass-to-charge value, they have been able to identify peptides for which the signals in the mass spectra were suppressed or hidden in the noise.

Off-line LC-MALDI, in contrast to on-line LC-ESI, offers the possibility to "freeze" the sample "in time", which again allows evaluation of the data, use of interactive data handling, and hypothesis-driven multistage MS. However, even without an LC system, a considerably increased sequence coverage can be obtained using interactive data handling combined with the optimization strategies described in this chapter.

5. Conclusion

Here we have presented some approaches that can enhance sequence coverage. The strategy described here is time consuming and not easy to automate. And even using this, complete characterization of a protein might not be possible at a proteomics sensitivity level especially because modified peptides of low stoichiometry might escape detection. The challenge in the future will be to quantify the degree of modification for a specific peptide. This will necessitate strategies for quantitative comparison between two peptides with totally different properties, the modified and nonmodified peptides. We expect that it will also be possible to solve this difficult task in the future.

Tutorial on tandem mass spectrometry database searching

Jimmy K. Eng
Institute for Systems Biology, Seattle, WA, USA

1. Introduction

With recent advances in search software and available databases, a novice can now easily perform a tandem mass spectrometry (MS/MS) sequence database search. Such a search requires an input spectrum, a sequence database to query, and a set of search parameters to guide the search. This tutorial will cover the mechanisms of performing an MS/MS search using the Mascot (Perkins *et al*., 1999) search engine for demonstration purposes.

Figure 1 illustrates the general process of sequence database searching. In general, an acquired tandem mass spectrum of a peptide is compared against theoretical tandem mass spectra of peptides generated in silico from the specified sequence database. The methods by which they are compared, that is, the mathematical scoring algorithms, vary widely between different database search engines such as Mascot, MS-Tag (Clauser *et al*., 1999), or SEQUEST (Eng *et al*., 1994; *see also* Article 3, **Tandem mass spectrometry database searching**, Volume 5). Nevertheless, the different search engines typically produce quite similar results, and the mathematical "behind the scenes" activity does not affect the fact that there are many features that are common and applicable to running a database search on most search engines.

2. Example spectrum to be interpreted

Figure 2 shows a raw, uninterpreted tandem mass spectrum of a peptide that will be used as the input for this exercise. The information derived from the input spectrum is the mass and intensity pairs that represent each peak in the fragmentation spectrum, the mass (1157 a.m.u.) of the precursor ion selected for MS/MS, and the charge state of the precursor ion, if known. The above spectrum was acquired on an ion trap mass spectrometer. The mass spectrometer used for acquisition determines the errors associated with the mass measurements and thus the mass tolerances to be used in the database search. Additionally, the instrument also determines the predominant peptide fragmentation products produced, thus guiding the selection of fragment ion types to consider in the search parameters.

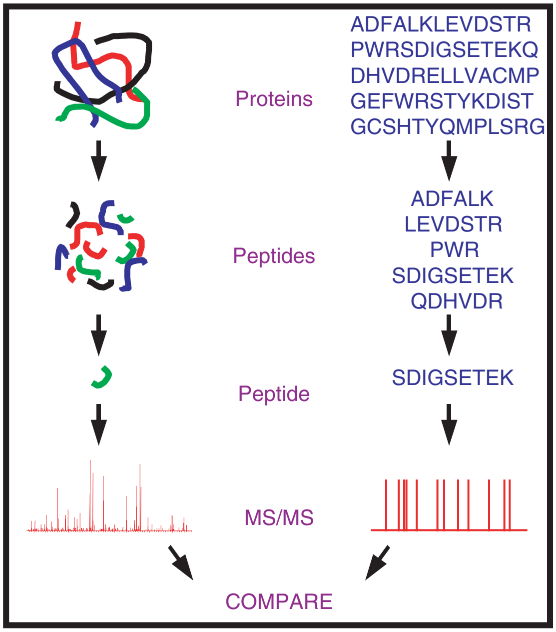

Figure 1 A schematic showing the concept of MS/MS database searching

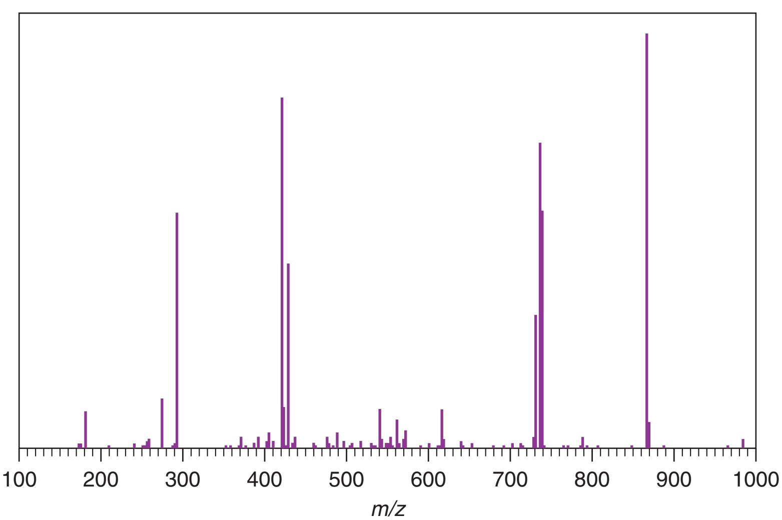

Figure 2 Example uninterpreted tandem mass spectrum. The displayed peak list, precursor ion charge state, and precursor or peptide mass are the input for an MS/MS database search

Any additional knowledge available about the input sample can enhance the potential success of the database search. Specifically, awareness of the organism from which the sample derives permits querying against a species-specific sequence database. Also, because the fragmentation spectra are from peptides, the protease used to digest the intact protein(s) is a valuable information that can be used either as part of the database search parameters, and thus part of the search, or as part of the validation of the search results. Finally, any process that changes the nature of amino acids in the sample such as metabolic labeling or chemical side chain modification, such as cysteine alkylation, must be incorporated into the search parameters (see below).

3. Search parameters

In our current example, there is no suspicion that the peptide is posttranslationally modified; thus, no modifications are specified in the initial query. If processing steps modify the sample, such as cysteine alkylation or metabolic labeling that incorporates an isotopically heavy amino acid, then these modifications should be specified in the search parameters. Modifications can typically be applied to any amino acid and/or the amino or carboxy terminus of a peptide.

Modifications typically are of two types. The first is the static modification that modifies all occurrences of a residue as would be expected with a covalent reaction that goes to completion or a metabolic labeling in which all residues are expected to be replaced. A second type of modification is the variable modification. This type of modification forces the search engine to look for two different forms of an amino acid. A common example is the search for phosphorylation where only a few percent of serine, threonine, or tyrosine residues are actually phosphorylated. In this case, the search is conducted allowing these residues to be either modified (+80 a.m.u.) or unmodified. Note that specifying this type of modification in the search parameters can significantly prolong search times.

The peptide associated with the spectrum in Figure 1 is from *Bos taurus* (cow), so this spectrum should ideally be searched against a database composed of *B. taurus* protein sequences. However, if the sample's species is not known or if the genome of that organism is poorly covered, then a more comprehensive sequence database composed of all species can be substituted, with the hope of finding an identical peptide in a related species. On-line search engines, such as Mascot or MS-Fit, supply a fixed set of sequence databases available for querying against. With a local search engine installation, both publicly available and proprietary sequence databases can be used for the database search.

Figure 3 displays a screen capture of the search parameters defined for this database search. As no cow-specific sequence database is available on the public Mascot search engine, a mammalian subset of the SwissProt (Bairoch and Apweiler, 1997) sequence database is selected. Trypsin is specified in the Enzyme field since trypsin was used to digest the original sample. This specifies that only tryptic peptides of this weight (1157 a.m.u.) in the database will be compared rather than all peptides of this weight. This will dramatically shorten the time required to complete a search. Neither static nor variable modifications are specified. An ESI-TRAP

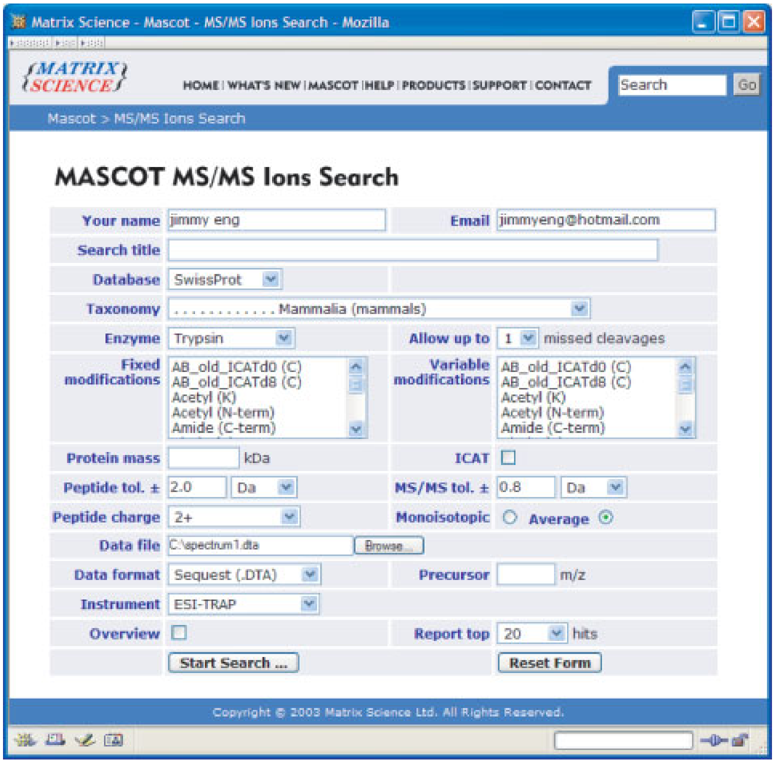

Figure 3 Example Mascot search parameters page. Primary parameter settings are the selection of the sequence database to query, modifications (if any), and acquisition instrument selection

is specified for the Instrument field; the selection of the instrument defines the fragment products to consider in the analysis. Mass tolerances of 2.0 a.m.u. and 0.8 a.m.u. are used for the peptide mass and fragment ion masses respectively. The performance of the mass spectrometer defines these mass tolerances used for the search.

4. Search results

The results of the search are shown in Figure 4. A description of the scoring algorithm and significance determination is beyond the scope of this tutorial but the Mascot search results show no positive identifications because the top ranked peptide, ADSVGKLLTVR received a probability-based MOWSE score of only 24. This score is below the suggested homology and identity significance thresholds of 32 and 41, respectively, for this particular input spectrum. In addition to having a nonsignificant score, the top ranked peptide is from a protein from *Mus musculus* (MCM7_MOUSE), whereas the input sample was from *B. taurus*.

There are many potential explanations and remedies for incorrect identifications from unsuccessful database searches. The correct sequence may not be in the

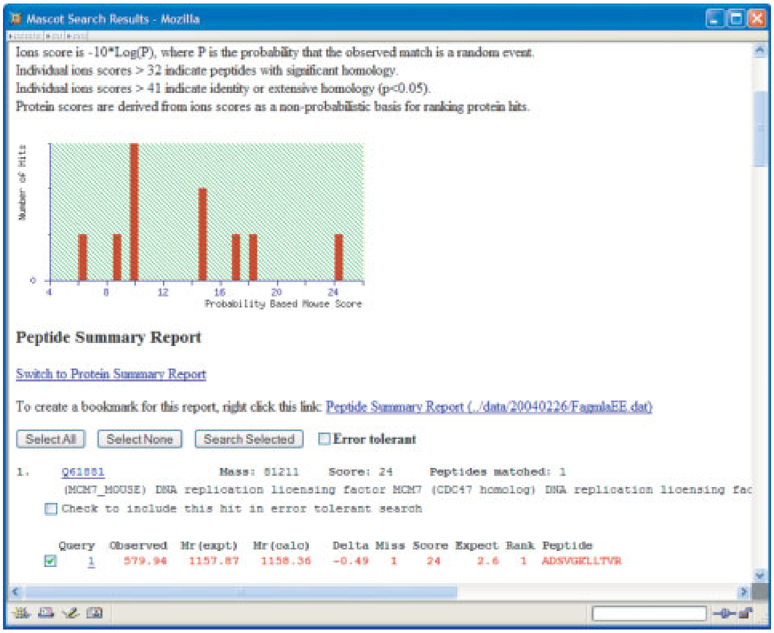

Figure 4 Mascot search results page. The top ranked peptide, ADSVGKLLTVR, was from the wrong organism and had a poor score, indicative of an incorrect identification

database that was queried; searching a larger or different sequence database might resolve the problem. The peptide could be posttranslationally modified, in which case adding common modifications might be considered in a subsequent search. It is possible that mass tolerances have been set too restrictively narrow with the effect of screening out the correct peptide. In this case, the database queried, lack of specified modifications, and narrow mass tolerances were not the culprits for the incorrect identification. The reason the spectrum failed to be identified correctly was due to the specification of the tryptic enzyme constraint. Even though the original sample was processed with trypsin to generate peptides, nontryptic peptides can exist either because of incomplete digestion, contaminating proteolysis, or in-source fragmentation. When removing the enzyme constraint, Mascot identified the peptide YQEPVLGPVR, a fragment tryptic at only the C-termini, from the protein bovine carbonic anhydrase (CASB_BOVIN). The peptide was identified as correct with a score of 72, compared to the suggested homology and identity thresholds of 49 and 61, respectively, as shown in Figure 5.

Figure 6 shows the overlay of calculated versus actual fragment ions for the peptide YQEPVLGPVR. This is a common view when validating search results because the matched spectrum should account for most of the peaks in the MS/MS spectrum (*see* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5). However, this validation process can be difficult and extremely subjective, depending on the quality of the input spectra and the experience of the user. One strategy to facilitate the validation process is to use background information on the input sample as a validation tool rather than a search constraint.

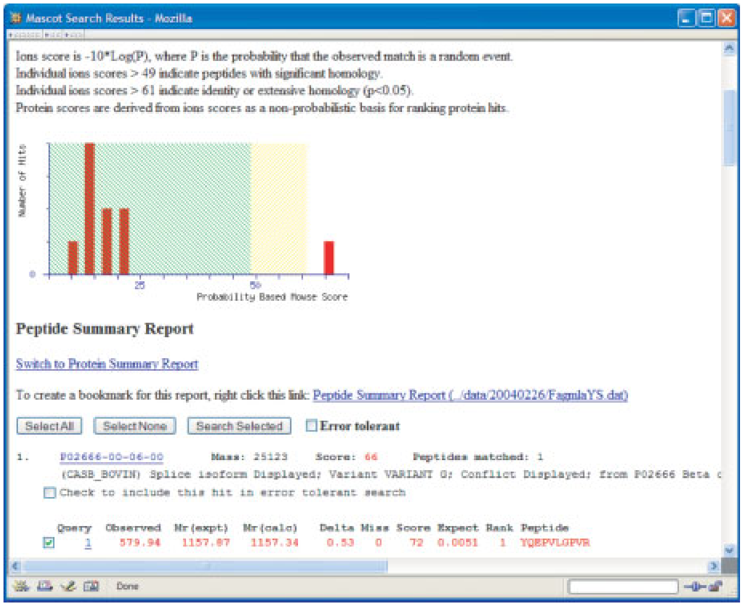

Figure 5 Mascot search results page. After modifying the search parameters to allow for peptides resulting from unexpected cleavage, the top ranked peptide, YQEPVQPVR, had a significant score and was identified from the correct organism

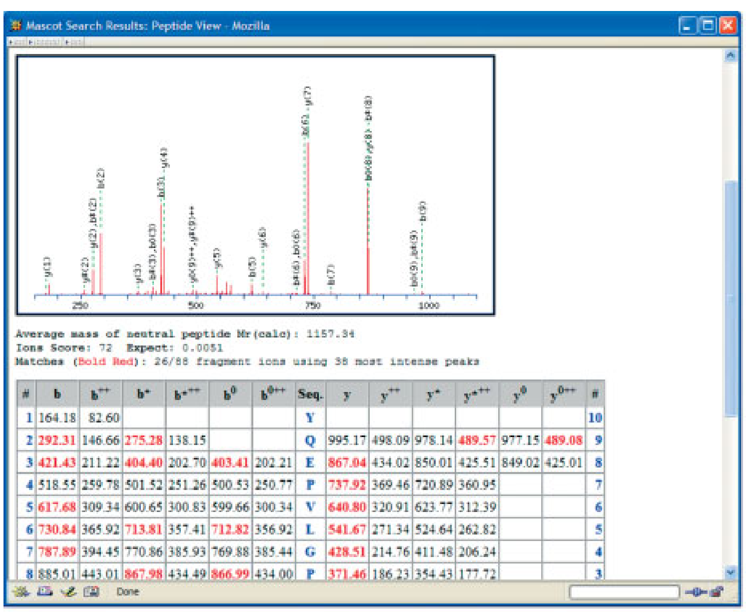

Figure 6 A typical spectral display view shows the extent of the match between input spectrum and identified peptide. Note how all of the major peaks are successfully accounted for

For example, the spectrum was identified out of a much larger database composed of all mammalian sequences as opposed to just searching a (smaller) bovine sequence database. The identification of a bovine protein supports the validity of the identification. Additionally, searching without an enzyme constraint can help the validation process because any peptide string from the sequence database can be analyzed (and not just the supposedly tryptic peptides that were generated in the protein digestion process). For an enzyme unconstrained search, high-scoring search results showing the expected tryptic or partially tryptic termini (as in this case) add confirmatory evidence.

5. Conclusions

Researchers new to the field who are interested in exploring proteomics should not be daunted by the complexity of tandem mass spectrometry. MS/MS database searching is an extremely powerful tool in the analysis of both simple and complex protein samples that couples the explosion of available genome sequence information with improvements in mass spectrometry instrumentation for rapid peptide and protein identification. With the efficiency of modern instrumentation and software, it is extremely easy to acquire and search a significant amount of MS/MS spectra, with the effect of shifting the burden of analysis to the validation process. As shown, the steps in performing an MS/MS database search are simple and straightforward. Likewise, search software has become user-friendlier to the neophyte. However, to achieve optimal results, new entrants to these techniques must educate themselves on the choices they make in both running a search (i.e., how search parameters impact the search results) and validating the search results.

Basic Techniques and Approaches

Techniques for ion dissociation (fragmentation) and scanning in MS/MS

Jack Throck Watson
Michigan State University, East Lansing, MI, USA

O. David Sparkman
University of the Pacific, Stockton, CA, USA

1. Introduction

Modern mass spectrometry techniques such as electrospray ionization (ESI) (*see* Article 10, **Hybrid MS**, Volume 5, Article 11, **Nano-MALDI and Nano-ESI MS**, Volume 5, and Article 75, **Mass spectrometry**, Volume 6) and atmospheric pressure chemical ionization (APCI) often only produce ions representing the intact molecule, usually protonated molecules (MH^+). Even when the mass of these ions is measured to an accuracy that will allow for a determination of the elemental composition, the identity of the molecule's structure is not necessarily forthcoming. Sometimes structural features of the ion representing the intact molecule can be deduced from the array of fragments formed. Both the mass of the fragments and the mass represented by the neutral loss that occurs when the ion fragments (the dark matter of the mass spectrum) are important in this process. Ions representing the intact analyte molecule produced by ESI and APCI have little or no internal energy to cause fragmentation. Therefore, it is necessary to energize these ions in order to gain the desired information.

Once formed, an ion can be made to dissociate by increasing its internal energy by any of several modes of excitation; these include collision-activated dissociation (CAD) (*see* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5) or collisionally induced dissociation (CID), surface-induced dissociation (again, involving a collision), photo-dissociation, and others. In this introduction, only CAD (same process as CID) will be considered. In CAD or CID, instrumental arrangements are available to control collisions between ions and molecules of a gas, for example, He, Ar, N_2, or any other inert gas. In some cases, the ion-molecule collisions are promoted in a collision cell, which is a relatively small volume within the instrument where the gas is confined, or it can be done in a large primary segment of the mass spectrometer. The extent to which the internal energy of an ion can be increased depends on the kinetic energy of the ion and the

relative masses of the ion and the gaseous molecule involved in the collision; this matter will not be addressed in this chapter.

In CAD, ions of a particular *m/z* value are selected (precursor ions) to collide with the collision gas molecules. Some instrumental provision is also available to determine the *m/z* values of the dissociation products (product ions) of these ion/molecule collisions, that is, there is one mass spectrometric means for selecting a precursor ion, and a second mass spectrometric means for analyzing the secondary ions (the product ions); thus, the overall instrumental technique is called mass spectrometry/mass spectrometry (MS/MS). The technique might consist of two separate mass spectrometers, "MS/MS-in-space", or it might be accomplished in a fixed coordinate of space, in which case, it is called "MS/MS-in-time"; these two modes of operation will be described in detail. There are several different operational or "scan modes" used in MS/MS analyses, for example, product-ion scan, precursor-ion scan, and neutral-loss scan; these different modes of scanning will be described together with the different types of information they provide.

Mass spectrometers determine the mass-to-charge ratio (*m/z*) of an ion (*see* Article 75, **Mass spectrometry**, Volume 6). Because mass is the principal parameter of interest, only ions of unit charge will be considered in this introductory description of MS/MS techniques. The technique of ion–ion collisions or reactions has been introduced recently as a means of reducing the charge state of multiple-charge ions; this technique will not be elaborated on here.

2. Instrumental configurations

2.1. MS/MS-in-space

Perhaps the simplest way to visualize MS/MS is to consider two mass spectrometers connected in tandem, whereby ion current resulting from ions of a specific *m/z* value (or values) selected by the first mass spectrometer passes into a collision cell, where CAD occurs; ion current, resulting from fragmentation (into product ions) as well as from residual precursors ions, passes out of the collision cell into the second mass spectrometer, where it is analyzed according to individual *m/z* values as recorded by a detector at the end of the second instrument. The triple-quadrupole mass spectrometer illustrated in Figure 1 is a manifestation of this MS/MS-in-space technology. The ions are selected in the first quadrupole (Q_1) mass spectrometer

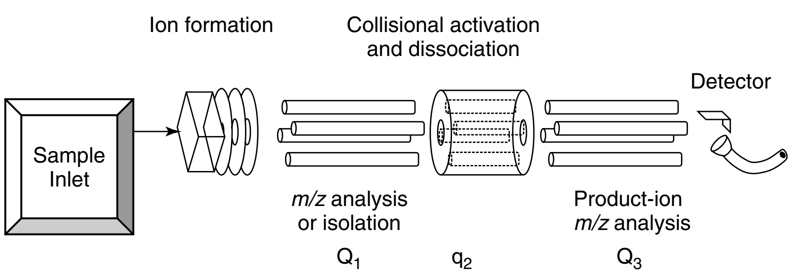

Figure 1 Schematic diagram of a triple-quadrupole mass spectrometer

(this instrument is not scanned), then passed to the second quadrupole (q_2), which is not mass-selective, that is, it is not a mass spectrometer, but rather it provides a means to "refocus" scattered ions in the collision cell where some of the precursor ions are transformed by CAD into product ions; all the ions leave the collision cell and enter the third quadrupole (Q_3) mass spectrometer where they are *m/z*-analyzed. These instruments are called *triple quadrupoles* because the originally developed concept used three quadrupole devices (*see* Article 8, **Quadrupole mass analyzers: theoretical and practical considerations**, Volume 5). In modern instruments that still use a quadrupole *m/z* analyzer for Q_1 and Q_3, the device constituting q_2, the collision cell, is something other than a quadrupole; it is usually a hexapole or octupole device or, as in the case of more recent instrumentation, a lens stack.

2.2. MS/MS-in-time

An increasingly common technique is to perform selection, dissociation, and analysis of secondary ions as a function of time in the same coordinates of space within a mass spectrometer. The quadrupole ion trap (QIT) (*see* Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5) mass spectrometer has become a popular instrument for conducting MS/MS-in-time; the ion cyclotron resonance mass spectrometer can also be used for this purpose, using technology commonly called FTMS (*see* Article 5, **FT-ICR**, Volume 5). An important limitation of MS/MS-in-time is referred to as the "low-mass cutoff". Product ions that have an *m/z* value of less than approximately one-third that of the precursor ion cannot be stored while CAD of the precursor ion is being carried out. An advantage of MS/MS-in-time over MS/MS-in-space is that only ions with the *m/z* value of the precursor ion are collisionally activated, meaning that secondary fragmentation is less likely to take place than in the collision cell of the MS/MS-in-space configuration, where product ions are also likely to undergo collisional activation and secondary dissociation.

3. Different "ion-scanning modes" for MS/MS with CAD

3.1. Product-ion scan

Probably the most commonly employed technique for MS/MS is one in which a particular precursor ion is subjected to CAD to obtain a product-ion mass spectrum to serve as a "fingerprint"; this MS/MS-in-space mode of operation is carried out essentially as described above. The MS/MS-in-time mode of operation in a quadrupole ion trap begins by transferring all the ions generated by a given sample into the trap, then adjusting the rf/dc parameters of the instrument to eject ions of all *m/z* values except those of the precursor. The normal operating pressure of the QIT is about the same as that of the collision cell in the triple quadrupole (0.13 Pa); therefore, if ions corresponding to the *m/z* value of the precursor ion are then excited, they will undergo collisions with the gas molecules in the trap and dissociate. The second step of the analysis begins by adjusting the rf/dc parameters

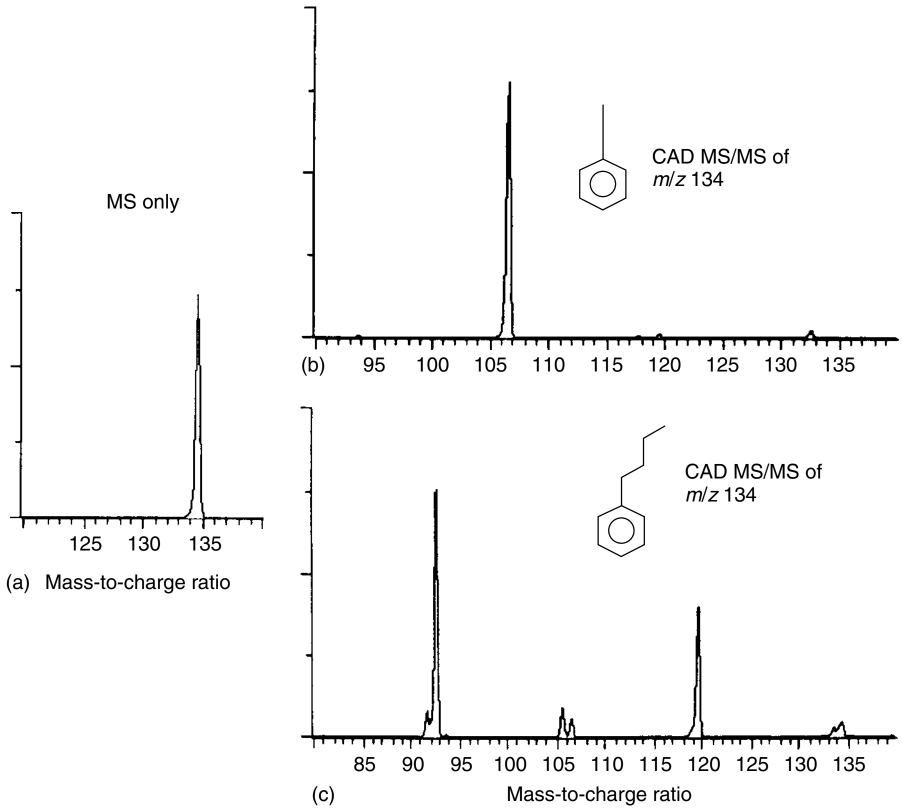

Figure 2 (a) Conventional mass spectrum (no CAD) of either *t*-butyl benzene or *n*-butyl benzene (each has a molecular ion peak at *m/z* 134 and no significant fragment ion peaks). (b) and (c) CAD MS/MS spectra of ion current at *m/z* 134 from *t*-butyl benzene and *n*-butyl benzene, respectively

of the instrument to accommodate ions through a large range of *m/z* values even though the precursor ions are the only ones in the trap; in this way, any nascent product ions produced during CAD of the precursor ions will be trapped as they are produced. The third step consists of a mass-selective ejection scan of the rf/dc parameters to obtain a mass spectrum of the product ions.

The power of the product-ion scan is demonstrated in a comparison of Figure 2(b) and (c), each of which is a product-ion spectrum of a precursor ion of *m/z* 134. Clearly, the pattern of peaks in the two product-ion mass spectra is different. In this way, the product-ion spectrum serves as a fingerprint for each of two compounds, each of which is capable of generating a precursor ion of *m/z* 134. Obviously, the ion of *m/z* 134 has a different structure in each case, which is the basis for the CAD product-ion spectra being different.

3.2. *Precursor-ion scan*

In this scan mode, the second mass spectrometer in the MS/MS-in-space configuration is held at a constant parameter (not scanned), while the first mass spectrometer

is scanned through a specified range of *m/z* values. In this way, an array of precursor ions can be assessed for their capacity to generate a product ion of a specific *m/z* value. An application of a precursor-ion scan is illustrated with the spectrum in Figure 3(b). From previous work, it was known that CAD of protonated peptides containing tyrosine produces the immonium ion of tyrosine at *m/z* 136, that is, the generation of such a product ion can be used as a marker for the presence of tyrosine in a peptide. In this application, the tryptic digest was analyzed by ESI CAD MS/MS by scanning the first mass spectrometer, while holding the second mass spectrometer constant at *m/z* 136; in this mode of operation, the detector produces a signal at a given *m/z* value only when the corresponding precursor ion in the scan of the first mass spectrometer is capable of producing an ion of *m/z* 136 in the collision cell. The complexity of the mixture in this application is represented in Figure 3(a), which is a mass spectrum obtained from analysis of the digest by direct infusion ESI-MS. Notice that the spectrum obtained during ESI-MS/MS with precursor scanning for *m/z* 136 (Figure 3b) is much simpler indicating that only four of the tryptic peptides (T4–T6, T14, and T16) contain tyrosine.

3.3. Neutral-loss scan

Under CAD conditions, some precursor ions are capable of expelling a molecule (the neutral dark matter), such as CO_2, methanol, and so on, in forming the product ion (*see* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5). This phenomenon of neutral loss can be exploited in detecting members of a family of such compounds during the analysis of a complex mixture by CAD MS/MS using the neutral-loss scan. The neutral-loss scan is accomplished by arranging a simultaneous scan of both mass spectrometers (one before, the other following the collision cell, where CAD takes place) offset from one another by a difference in *m/z* values equal to the mass of the molecule expelled from the precursor ions of interest. An application of a neutral-loss scan is illustrated in Figure 3(c). From previous work, it was known that double-protonated peptides containing methionine eliminated CH_3SH (48 Da) during CAD. The spectrum in Figure 3(c) indicates that only two of the tryptic peptides, namely, T2 and T11, among the 20 or so peptides represented in the top spectrum from nonspecific analysis of the digest contain methionine; the data for Figure 3(c) were recorded by scanning Q_1 and Q_3 offset by 24 *m/z* units (mass of 48 Da divided by charge of 2).

It is important to note that the precursor-ion scan and the neutral-loss scan can only be carried out using MS/MS-in-space. These two modes of operation are not possible with MS/MS-in-time. When one of the *m/z* analyzers in an MS/MS-in-space instrument is a nonscanning mass spectrometer, such as a time-of-flight (*see* Article 10, **Hybrid MS**, Volume 5) *m/z* analyzer, the neutral-loss scan mode is not possible because the second analyzer does not scan and, therefore, cannot have a scan offset.

Another important mode of operation for MS/MS is the selected reaction monitoring (SRM) mode. This mode is used for quantitation and specificity. Q_1 is held at a fixed value to allow precursor ions of the specified *m/z* value to pass into the collision cell (q_2). Q_3 is held at a fixed *m/z* value to allow only product

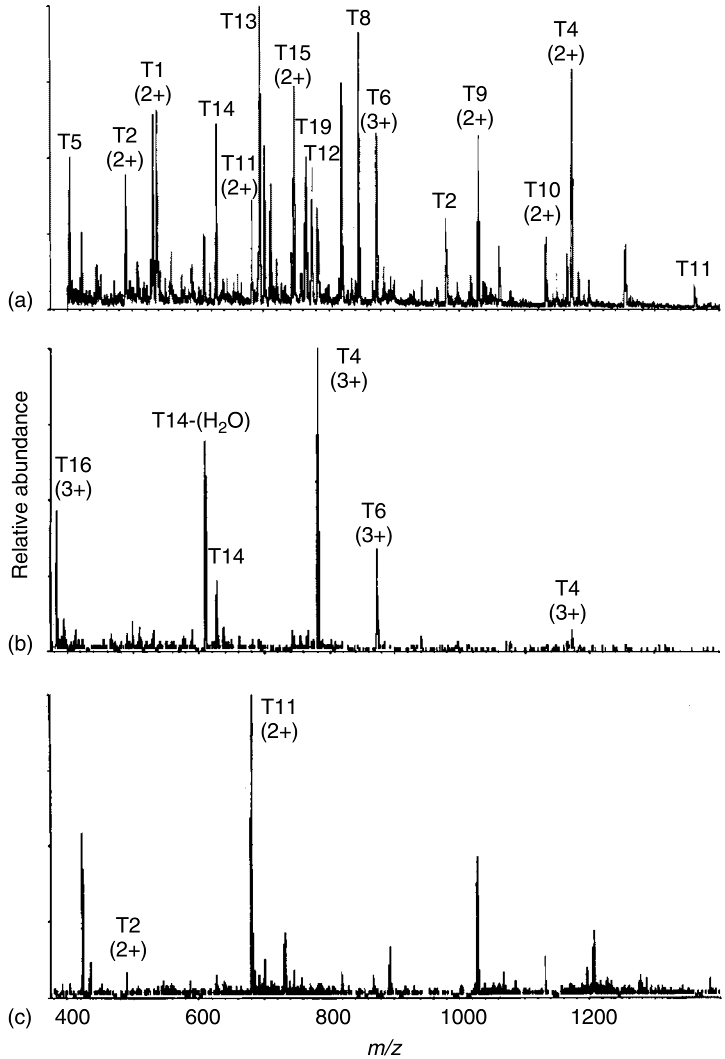

Figure 3 Two examples of results from specialized uses of CAD MS/MS spectra. (a) Conventional electrospray mass spectrum (MS only, no CAD MS/MS) resulting from infusion (no chromatography) of a mixture of tryptic peptides into an electrospray ionization triple-quadrupole mass spectrometer; numbers in parentheses indicate charge state of the corresponding ion. (b) Precusor-ion mass spectrum of the same mixture acquired under conditions allowing detection of only those precursors capable of generating a product ion of *m/z* 136 (immonium ion of tyrosine = 136 Da). (c) Neutral-loss mass spectrum of the same mixture acquired at an offset in *m/z* value between Q_1 and Q_3 to allow detection of only those precursors capable of expelling CH_3SH (48 Da) indicating the presence of methionine in the side chain. (Reprinted by permission of Springer-Verlag, 2001)

ions of a specific mass to reach the detector. In this way, specificity is achieved because only ions that undergo a transition from *m/z* A to *m/z* B in the collision cell will reach the detector; peak area integrated from the product-ion signal provides quantitative information.

4. Summary

CAD can provide characteristic, if not unique, fragmentation (into product ions) of a precursor ion. A variety of scan modes is available with MS/MS instrumentation to permit selective detection of certain compounds depending on the CAD behavior of the precursor ions.

Making nanocolumns and tips

Claire Delahunty and John R. Yates III
The Scripps Research Institute, La Jolla, CA, USA

The successful production of nanocolumns and tips is vital to the success of an in-line multidimensional LC-MS/MS analysis (*see* Article 13, **Multidimensional liquid chromatography tandem mass spectrometry for biological discovery**, Volume 5). Making nanocolumns for LC/LC-MS/MS is a two-step process: first, fused-silica microcapillary tubing is heated and pulled to produce a column with a tip diameter of 2–5 µm, then the column is packed with chromatographic packing material. The choice and volume of packing materials can vary depending on the complexity of the sample, the volume of the sample, and the goal of the separation, but the optimal diameter of the column tip is the same for all electrospray applications. Typically, the flow rate required for the direct analysis of proteins with femtomole scale sensitivity is 200–300 nL min^{-1}. To achieve this, nanocolumns should have a 50–100 um ID, with a tip ID of approx. 5 um. Columns with smaller IDs can clog easily; those with larger IDs result in less-efficient electrospray.

Nanocolumns may be reproducibly pulled using a commercial CO_2 laser puller (Sutter Instruments, Novato, CA), but prepulled columns can also be purchased (i.e., New Objective, Woburn, MA). By pulling the capillary at the midpoint of its length, two nanocolumns are produced from one 50–54 cm length of capillary tubing. Before placing the capillary in the puller, the polyimide coating must be burned off a 1-in. center section using an alcohol burner. Bunsen burners should not be used since they burn hotter and can seal the capillary. If the column is not properly pulled, packing material will not load smoothly and chromatography will be poor. The parameters for pulling optimal tips vary from instrument to instrument and need to be determined experimentally. Some typical values are listed in Table 1. A detailed discussion of these parameters and their role in capillary construction is given in the Sutter Instrument P-2000 manual.

Packing materials are loaded onto the nanocolumns through the use of a stainless steel pressurization device or "bomb" (The Scripps Research Institute, and Cytopea, Inc., see Figure 1). This bomb is attached to a helium tank with a high-pressure line and valve. The bomb has a removable lid and the lid and the base each has a groove that holds a viton O-ring to ensure a high-pressure seal when the lid is tightened down. The lid is tightened to the base with five bolts. A Swagelock fitting is located in the center of the lid. This fitting holds a Teflon ferrule that allows the capillary to be inserted down into the bomb and into the microfuge tube. The Teflon ferrule can be tightened to hold the capillary in place and provide a high-pressure

Table 1 Typical parameters for pulling a nanocolumn from 100 × 365-μm fused-silica capillary tubing

	Heat	Filament	Velocity	Delay	Pull
1	270	0	30	128	0
2	320	0	40	200	0
3	310	0	30	200	0
4	290	0	20	200	0

Figure 1 Pressure loading device that can be used to pack nanocolumns and to load samples onto nanocolumns

seal. The packing material is suspended in methanol and is placed in a microfuge tube that stands upright in the center of the bomb.

For analyzing simple mixtures of proteins, a one-dimensional nanocolumn can be used. In this case, 10–15 cm of C_{18} reversed-phase (RP) packing material is loaded into the column. However, for more complex mixtures, a biphasic column is employed in which a 7-cm section of RP material is flanked upstream by 3 cm of strong cation exchange (SCX) resin. This configuration allows for multidimensional separation of peptides because peptides are loaded onto and bound to the SCX resin and sequentially "stepped" off with salt pulses, followed by reverse-phase separation of each subset of peptides. Many samples contain competing salts that interfere with the interaction of the peptides with the SCX resin. In these

cases, off-line desalting can be performed using a solid-phase extraction column. Alternatively, peptides can be desalted online using a second phase of reverse-phase packing material directly upstream from the SCX. In this method, peptides can be loaded directly onto the column, desalted in the first cycle of the analysis and subjected to multidimensional separation in the subsequent steps. Comparison of single-dimensional, two-phase, and three-phase LC-MS/MS (McDonald *et al*., 2002) has shown a dramatic increase in the number of peptides identified in the multidimensional runs versus the single dimensional. A larger but less dramatic increase in the number of peptides identified is seen in a three-phase run versus a two-phase. In particular, more hydrophilic peptides are observed in a three-phase column.

Preparation of the nanocolumn:

1. Cut a 50–54 cm length of 100 × 365-µm fused-silica capillary tubing. Hold the center of the tubing over an alcohol burner and burn the polyimide coating off a 5–10 cm section. Remove the charred material by cleaning with a Kimwipe soaked in methanol. The tubing should be clear in this section.
2. Place the length of tubing in the P-200 laser puller so that the clear section is in the mirrored chamber of the puller. In this position, the laser is focused on the center of the tubing and the fused silica can be melted.
3. Select the program on the laser puller that will result in a 3–5 µm ID tip. The heating program should be repeated three times before the tubing is pulled.

Packing the column:

1. Place a small amount (5 mg) of C_{18} RP packing material (5-µm Polaris C_{18}-A or similar) in a microcentrifuge tube and add 1 mL of methanol. Agitate the tube to create a slurry of the packing material.
2. Place the open microcentrifuge tube into the stainless steel bomb and secure the lid by tightening the five screws.
3. Insert the flat end of the pulled capillary column through the ferrule until it reaches the bottom of the microcentrifuge tube. Tighten the ferrule until the capillary does not move when gently tugged.
4. Adjust the pressure on the helium tank to 400–800 psi. Slowly pressurize the bomb by opening the valve on the high-pressure line. If the bomb is pressurized too rapidly, the microcentrifuge tube can rupture.
5. When the pressure is applied to the bomb, packing material should begin to rise and fill the capillary. If packing material stops filling the capillary before 7–10 cm have been packed, release the pressure on the bomb, loosen the ferrule holding the capillary and gently tap the capillary on the bottom of the microcentrifuge tube. Re-tighten the ferrule and repressurize the bomb. Continue packing until the desired amount of packing material is loaded.
6. If a two- or three-phase column is to be made, release the pressure on the bomb and remove the capillary column. Open the bomb and replace the C_{18} packing material with a microcentrifuge tube containing a methanol slurry of SCX (5-µm Partisphere strong cation exchanger, Whatman) packing material.

7. Repressurize the bomb and load 3 cm of SCX packing material. For a three-phase column, repeat the procedure, but load 3 cm of C_{18} packing material.

Tutorial

Tutorial on protein fingerprinting

Fredrik Levander
Lund University, Lund, Sweden

1. Introduction

Mass spectrometry-based protein identification is one of the core techniques in proteomics. It is based on the comparison of peaks in mass spectra with calculated theoretical masses for proteins as derived from their primary structure. By cutting the protein to identify with a specific endoprotease or chemical reaction, a mixture of peptides is generated. The peptide masses are measured in a mass spectrometer. The cutting procedure is then simulated on all proteins in a protein sequence database and the theoretical mass fingerprints generated are compared to the one acquired on the mass spectrometer (Figure 1). For reviews on protein fingerprinting, also known as peptide mass fingerprinting, see (Henzel *et al*., 2003) and Article 12, **Protein fingerprinting**, Volume 5. Peptide fingerprinting, or peptide fragment fingerprinting, is based on similar principles, but instead of measuring the peptide masses only, the individual peptides are fragmented in the mass spectrometer yielding peptide fragment fingerprints. Peptide fingerprinting is reviewed elsewhere in this encyclopedia (*see* Article 3, **Tandem mass spectrometry database searching**, Volume 5), and there is a separate tutorial on the subject (*see* Article 17, **Tutorial on tandem mass spectrometry database searching**, Volume 5). Nevertheless, there are several points mentioned below that are valid also for peptide fingerprinting.

For satisfactory protein identification it is important to consider the different steps of the workflow since there are several factors that are important to achieve a successful identification. This tutorial will give an overview of the process and some hints on how to succeed with protein fingerprinting.

2. Experimental setup

A working experimental setup is the first key to success and sample preparation is described thoroughly in Article 14, **Sample preparation for MALDI and electrospray**, Volume 5. The most basic prerequisite is that there has to be sufficient protein for the analysis. Trypsin digestion of the sample will work well only if the protein concentration is sufficient. Nowadays this is more critical than the sensitivity of the mass analyzers as the mass spectrometers are usually sensitive enough. An efficient digestion is important for extraction of the protein fragments from gel

Figure 1 Theoretical tryptic digest of a protein. The arginines and lysines are marked in gray in the amino acid sequence

slices. If the protein is still in the gel, there will not be any sample signal, no matter how sensitive the mass spectrometer is. It is even more important for the actual fingerprinting to have as complete cleavage as possible. Some missed cleavages are inevitable, but if two or more have to be considered for each peptide, there will be too many possible masses for efficient identification of most proteins. Efficient sample ionization and sensitive and well-calibrated mass analysis are as important for the analysis. For protein fingerprinting, currently the standard mass spectrometer is of the matrix-assisted laser desorption ionization-time-of-flight (MALDI-ToF) type, *see* Article 7, **Time-of-flight mass spectrometry**, Volume 5.

3. Peak extraction and deisotoping

When the mass spectra have been acquired, the first task is to convert the spectra into peak lists. Mass spectra are a mixture of sample signal and noise and it is not straightforward to do the peak picking. Every peptide will yield a cluster of peaks due to the isotopic distribution, and only the monoisotopic peak should be used for the fingerprinting, see Figure 2. As illustrated in Figure 2 it is often quite easy to select the strongest peaks, but on the lower end of the scale, it is almost impossible to differentiate signal from noise. Peak extraction is normally performed using computer software, which is most often bundled with the mass spectrometer. The peak picking software work quite differently and they also have parameter settings, which will influence the results. If the algorithms are set to be very sensitive they usually extract more background as well as more sample peaks. This can be good in some and bad in other cases, therefore it is worthwhile to search with several peak lists extracted from the same mass spectrum (Rögnvaldsson *et al*., 2004).

4. Peak lists filtering

Mass spectra also contain matrix or solvent peaks depending on the ionization source, and in addition peptide peaks derived from contaminants such as trypsin autolysis peaks and keratins are common in the samples. It is a good idea to remove as many of the contaminant peaks as possible, provided they can be identified. Still, removal of sample peaks is undesirable and it is sometimes worthwhile to search

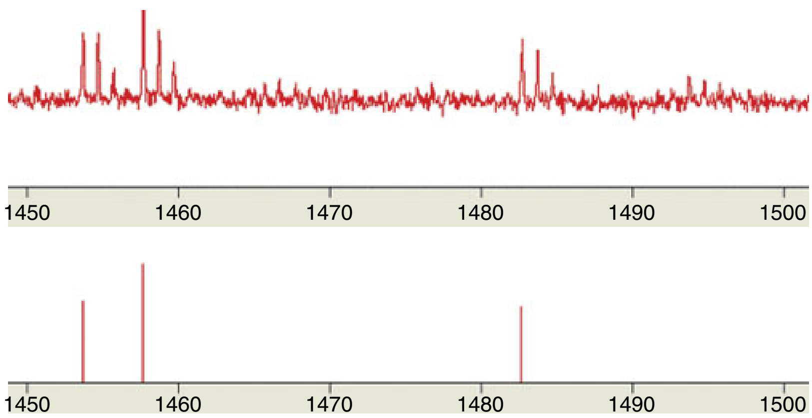

Figure 2 Raw MALDI-ToF spectrum and selected monoisotopic peaks with signal-to-noise threshold set at 2.0. The *x* axis is *m/z* and *y* is the signal intensity

both using the raw peak list and a filtered peak list. Basic filters for trypsin are often included in the database matching programs, but for more extensive filtering one will have to find out what contaminants are often present in the lab by overlaying peak lists. This can be performed manually or automatically (Levander *et al*., 2004).

At the same time as performing the filtering of peak lists, the identified contaminants can also be used to recalibrate the spectra, if this is not automatically included in the database search, as it is in the Aldente search engine, for example, (**www.expasy.org/tools/aldente/**).

5. Database searching

There are numerous different computer programs that perform matching of the peak list with theoretical peak lists derived from the protein database (*see* Article 12, **Protein fingerprinting**, Volume 5). The matching itself is trivial, and the difference between the different algorithms is rather on the scoring level. If all peaks in a spectrum would match all theoretical peaks of a protein, there would not be much ambiguity in the identification process. However, the normal result is that only a fraction of the peaks match, and that many of the theoretical peaks cannot be found in the spectrum or are outside the mass range for which spectra are acquired. There will be some peak matches to many proteins, and the scoring algorithm will try to tell, which is the best protein candidate for the peak list. The algorithms should also account for the possibility that there are several proteins in the sample. It is desirable to have some kind of measure of how likely the protein hit is to be random or correct, and probability-based algorithms should preferentially be used. Mascot from Matrix Science (**www.matrixscience.com**) is probably the most used search engine today, but several other search programs also provide probabilistic scoring.

Irrespective of the choice of database search program, there are several important parameters to set:

The choice of database is most critical. If the protein or a closely related one is not in the database the search will not be successful. If the analyzed protein is from an organism with a sequenced and annotated genome, one can opt to search only that proteome. A problem that can arise is that the protein has not been correctly annotated even if the genome sequence is published. Sometimes searching also in sequences from related organisms can be helpful. It is also possible to find conserved proteins even for organisms that have not been sequenced if the sequence similarity to a known protein is high enough. It is also a good idea to search a large protein database with proteins from several organisms, since it is quite unlikely that a protein from the organism analyzed ends up as a top candidate by chance.

Mass tolerance is an important factor. The mass accuracy of the mass spectrum determines how small the search window can be, that is, which mass error can be tolerated for a peak match. If the mass tolerance window is small, fewer proteins will have to be scored, since there will be fewer random matches than with a large mass error. On the other hand, if the mass window is set too small, one will risk missing hits when the calibration is worse than expected. It is so often that the mass calibration varies quite a lot over a MALDI target plate, and it is necessary to perform several searches with different mass tolerances to find the right protein. Some scoring algorithms utilize the fact that the mass error tends to be linear and makes a correlation of the error which is included in the score (Egelhofer *et al*., 2002, Gasteiger *et al*., 2005).

Amino acid modifications to consider have to be marked.Chemical modification of amino acids will change the mass for a peptide, and if it is not considered, the peptide mass will not be matched. Fixed amino acid modifications are those that can be expected to be true for all (or most) amino acids of one kind, for example, reduction and alkylation of cysteins in 2D gels will impose carbamidomethylation. Variable modifications are those that appear on some amino acids, but not all. Methionine oxidation is a modification that is very frequent and variable methionine oxidation is of a standard setting. There are many natural modifications of proteins, and it could be teasing to set some of these as variable in the search. However, for each variable modification the number of possible masses quickly rises for a peptide, and this makes the search less specific. If a peptide contains a few amino acids that could all be modified independent of each other, the number of combinations rises quickly.

Finally, missed cleavages for the enzyme should be considered, but as for the variable modifications, the number of possible masses quickly rises if many missed cleavages are allowed.

6. Validation of the results

The protein fingerprinting experiment will usually return one or more candidate proteins with scores. The main task is then to determine which hits are true and which are false. To start with one can set a score cutoff in which the false-positive occurrence is within tolerable levels for the particular experiment. A hit that does

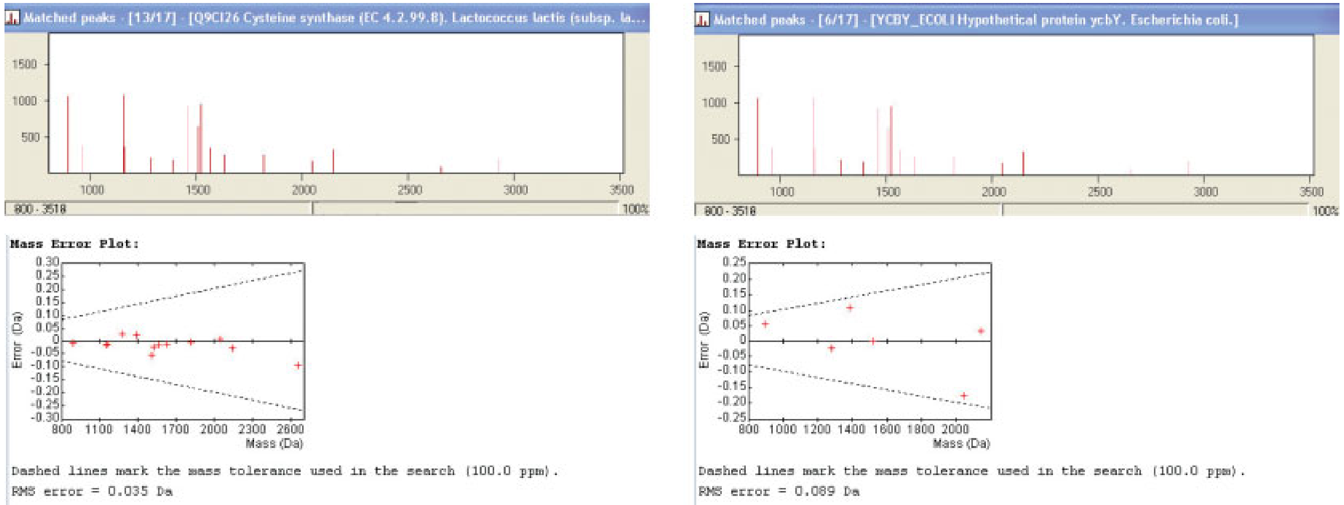

Figure 3 Database matches with a MALDI-ToF peak list. In the spectra the matched peaks are in dark red and the unmatched peaks in light red. To the left is the correct hit. The large spectrum peaks are covered in the match and the mass error is linear. Fifty percent of the protein sequence was covered (not shown). To the right is a false hit. Even though some of the large peaks are covered, the protein coverage is only 11% and the mass error is irregular

not pass the cutoff but has a good score can then be manually inspected with regard to factors that were not included in the scoring of the search program. If the strong peaks in the spectrum match the protein and the mass error is systematic these are good indications of a true protein hit (Figure 3). Tryptic peptides with a *C*-terminal arginine are usually quite strong too. However, for certainty, validation with peptide fingerprinting is often required.

Introductory Review

Separation-dependent approaches for protein expression profiling

Michael J. Dunn and Stephen R. Pennington
Proteome Research Centre, University College Dublin, Conway Institute for Biomolecular and Biomedical Research, Dublin, Ireland

1. Introduction

Intense efforts over the last few years have resulted in the availability, at the time of writing (February 2005), of complete genome sequences for 256 organisms (21 archael, 203 bacterial, 32 eukaryotic), including man. This wealth of information is an invaluable resource that will allow comprehensive studies of gene expression that will in turn lead to new insights into cellular functions that determine biologically relevant phenotypes in health and disease. The understanding that one gene can encode more than a single protein has led to a realization that the functional complexity of an organism far exceeds that indicated by its genome sequence alone. While powerful techniques such as DNA microarrays and serial analysis of gene expression (SAGE) make it possible to undertake rapid, global transcriptomic profiling of mRNA expression, processes including alternative mRNA splicing, RNA editing, and co- and posttranslational protein modification make it essential to undertake expression studies at the protein level. The concept of mapping the human complement of protein expression was first proposed more than 25 years ago (Anderson and Anderson, 1982), with the development of a technique in which large numbers of proteins could be separated simultaneously by two-dimensional polyacrylamide gel electrophoresis (2-DE) (O'Farrell, 1975). The term "proteome" was not established until the mid-1990s (Wasinger *et al*., 1995) when it was proposed to define the protein complement of a genome. This article will give an introduction to expression profiling in which the individual proteins in a complex sample are separated prior to semiquantitative analysis, and then identified usually using techniques of mass spectrometry. For an introduction to alternative strategies for expression profiling of unresolved complex protein samples, see Article 21, **Separation-independent approaches for protein expression profiling**, Volume 5.

2. Two-dimensional gel electrophoresis (2-DE)

The technique of two-dimensional gel electrophoresis (2-DE) in which proteins are separated in the first dimension according to their charge properties (isoelectric point, pI) under denaturing conditions, followed by their separation in the second dimension according to their relative molecular mass (M_r) by sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE) was developed more than 25 years ago (O'Farrell, 1975). Nevertheless, it remains the core technology of choice for the majority of applied proteomic projects (Görg *et al*., 2004; *see also* Article 22, **Two-dimensional gel electrophoresis**, Volume 5 and Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5) due to its ability to separate simultaneously thousands of proteins and to indicate posttranslational modifications that result in alterations in protein pI and/or M_r. Large-format (24 × 21 cm) 2-D gels can routinely separate around 2000 protein spots. Moreover, recent developments including the use of narrow range "zoom" gels (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5 and Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5) and fluorescent dyes that facilitate the multiplex analysis of samples (*see* Article 25, **2D DIGE**, Volume 5 and Article 30, **2-D Difference Gel Electrophoresis – an accurate quantitative method for protein analysis**, Volume 5) make it possible to achieve greater proteomic coverage combined with more accurate differential expression analysis. Additional advantages of 2-DE are the high-sensitivity visualization of the resulting 2-D separations (*see* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5), compatibility with quantitative computer analysis to detect differentially regulated proteins (Dowsey *et al*., 2003; *see also* Article 26, **Image analysis**, Volume 5), and the relative ease with which proteins from 2-D gels can be identified and characterized by mass spectrometry (*see* Article 31, **MS-based methods for identification of 2-DE-resolved proteins**, Volume 5).

3. Alternatives to 2-DE

Despite the many advantages of 2-DE, there are alternative protein separation strategies. Perhaps the simplest alternative to 2-DE is the use of one-dimensional SDS-PAGE to separate proteins in the sample, on the basis of their M_r followed by protein identification by tandem mass spectrometry (MS/MS), such that several proteins comigrating in a single band can be identified. This method is limited by the complexity of the protein mixture that can be analyzed but is well suited for the analysis of membrane proteins, and has also been successfully applied to the study of protein complexes (Figeys *et al*., 2001). Other approaches avoid the use of gels altogether by combining liquid chromatography (LC) and MS. In these so-called shotgun approaches, a tryptic digest of the sample is separated by one or more dimensions (typically ion-exchange combined with reverse-phase) of LC to reduce the complexity of peptide fractions. These are subsequently introduced (either on- or off-line) into a tandem mass spectrometer for sequence-based identification. For example, the so-called MudPIT approach (Wolters *et al*., 2001) identified around

1500 yeast proteins in a single analysis (Washburn *et al*., 2001). An alternative to this approach that is more robust than multidimensional chromatography, while still allowing complex samples to be analyzed, has been termed *GeLC-MS/MS* (Schirle *et al*., 2003). Here, tryptic digests of protein bands excised from the SDS-PAGE gel are separated by one-dimensional RP-HPLC prior to on- or off-line MS/MS analysis. However, a major limitation of such approaches is that unless combined with some form of stable isotope labeling or "mass tagging", they provide no information on semiquantitative abundance of proteins and are very limited in their ability to detect posttranslational modifications.

The former problem is currently being addressed by the development of a range of MS-based techniques in which stable isotopes are used to differentiate between two or more populations of proteins (Han *et al*., 2001). In general, this approach consists of four steps: (1) differential isotopic labeling of the two (or more) protein mixtures, (2) digestion of the combined labeled samples with a protease such as trypsin or Lys-C, (3) separation of the peptides by multidimensional LC, and (4) semiquantitative analysis and identification of the peptides by MS/MS. Currently, the most widely used method is the isotope-coded affinity tag (ICAT) (Han *et al*., 2001; *see also* Article 23, **ICAT and other labeling strategies for semiquantitative LC-based expression profiling**, Volume 5), but there are a variety of other approaches involving labeling with stable isotopes at the whole cell, intact protein, or tryptic peptide level (Julka and Regnier, 2004; Ross *et al*., 2004; *see also* Article 23, **ICAT and other labeling strategies for semiquantitative LC-based expression profiling**, Volume 5). Although these approaches are promising, there are caveats: (1) their quantitative reproducibility needs to be established, (2) the dynamic range of the these techniques may be little better than 2-DE, and (3) there is evidence that they can be complementary to a 2-DE approach in identifying a different subset of proteins from a given sample (Kubota *et al*., 2003).

4. Conclusion

The current array of proteomic techniques makes it possible to characterize global alterations in protein expression associated with the progression of many different biological processes, including human disease. However, there is still no one method that is suitable for the analysis of all samples, and for many projects it is likely that a combination of proteomic platforms, both gel and nongel based, will have to be applied to provide the required depth of proteomic coverage.

Introductory Review

Separation-independent approaches for protein expression profiling

Rosalind E. Jenkins

1. Introduction

The completion of the Human Genome Mapping Project (see for example **www.ornl.gov/sci/techresources/Human_Genome/project/progress.shtml**, **www.sanger.ac.uk/HGP/**, **www.tigr.org/tdb/**) plus many others has the potential to accelerate our understanding of the biology of these organisms. One of the most successful tools developed to exploit this new information is the cDNA or oligonucleotide microarray, capable of analyzing the relative level of transcription of thousands of genes simultaneously on a format not much larger than a postage stamp (Duggan *et al*., 1999; Schena *et al*., 1995; *see also* Article 90, **Microarrays: an overview**, Volume 4). Such transcriptomic studies have provided insights into the development of cancer (Liang and Pardee, 2003; Ntzani and Ioannidis, 2003) and infectious diseases (Bryant *et al*., 2004), and aided in the assessment of the toxicity profiles of drugs (Shaw and Morrow, 2003). However, as such methods have become more routine and are in more widespread use, it has become clear that they have to be complemented by the direct analysis of the functional end products of the genes – the proteins. There are several reasons for this: first, the correlation between the level of an mRNA and its encoded protein is frequently poor; second, there are biological samples that are not suitable for mRNA expression analysis, such as plasma and urine; and third, it is not only the expression level of a protein that determines cell fate but also factors such as the subcellular localization, the degree and type of posttranslational modification, and the interaction of the protein with other biomolecules. Currently, analysis of protein expression often involves labor-intensive and low-throughput techniques such as two-dimensional gel electrophoresis (*see* Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5) and multidimensional liquid chromatography (*see* Article 13, **Multidimensional liquid chromatography tandem mass spectrometry for biological**

discovery, Volume 5), but the field of proteomics would be revolutionized if protein microarrays analogous to DNA microarrays could be developed (*see* Article 24, **Protein arrays**, Volume 5, Article 32, **Arraying proteins and antibodies**, Volume 5, and Article 33, **Basic techniques for the use of reverse phase protein microarrays for signal pathway profiling**, Volume 5). This review describes the basic construction of high-density microarrays and highlights some of the issues arising from the exploitation of the technology for high-throughput protein analysis.

2. Protein versus antibody arrays

Protein arrays are those in which the capture reagent is a peptide or a protein other than an antibody, and one of their main applications is to investigate functional interactions (Figure 1). Protein arrays may be used to investigate potential drug targets or determine substrate binding to enzymes. These arrays may be reversed so that multiple peptides or chemical libraries are immobilized and the array is probed with a single protein of interest. For example, peptides containing consensus phosphorylation sites may be arrayed and incubated with a kinase in the presence of radiolabeled ATP: autoradiography then reveals which peptides have been phosphorylated and provides clues as to the substrate specificity of the kinase (MacBeath and Schreiber, 2000). As a result of progress in genome sequencing, researchers are now able to generate libraries of recombinant proteins that represent a substantial proportion of an organism's proteome and these may be cloned, expressed, and spotted onto an array surface in an automated manner (Schweitzer *et al*., 2003; Walter *et al*., 2000; *see also* Article 24, **Protein arrays**, Volume 5 and Article 32, **Arraying proteins and antibodies**, Volume 5). One application of this approach is to investigate protein–protein interactions on a proteome-wide scale, thereby determining the organism's "interactome". Other applications of the recombinant protein array include screening of manufactured antibodies for specificity and as a diagnostic tool by detecting disease-specific antibodies in human plasma (Lueking *et al*., 2003). There are some limitations to this approach, not least of which is the fact that bacterially expressed proteins are not posttranslationally modified in the same way as those expressed in mammalian cells, and this may affect their interaction with other proteins. However, other sources of protein may be exploited. For instance, protein extracted from a prostate cancer cell line has been fractionated, spotted onto nitrocellulose-coated slides, and used to profile the antibody repertoire in prostate cancer patients (Bouwman *et al*., 2003).

Antibody arrays are those in which the capture reagents immobilized on the array surface are themselves antibodies and they are used as a means of monitoring protein expression changes within the test samples (Figure 2). They are thus designed to perform the same sort of proteomic analysis as comparative two-dimensional gel electrophoresis (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5 and Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5) but in a much higher throughput manner, and are more analogous to DNA microarrays than the protein arrays described above. Protein profiling via antibody microarrays has great potential as a discovery tool, particularly in the field of cancer research. Preliminary studies of oral squamous cell carcinoma (Knezevic *et al*., 2001), prostate

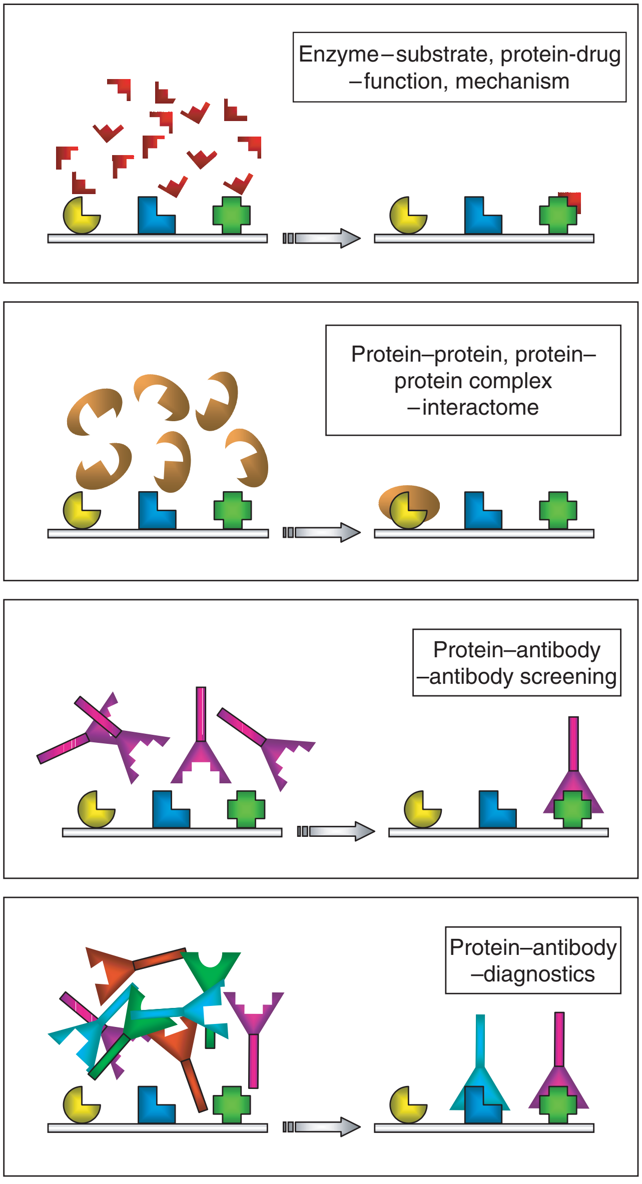

Figure 1 Schematic of protein arrays and their potential applications. A range of proteins other than antibodies are immobilized on a solid support in an addressable format and they are screened for interactions with a variety of samples. They may be probed with complex mixtures of other proteins or biological molecules, or with synthetic moieties such as drugs. This may provide insights into protein function, aid in the development of new drugs, or provide tools for the clinic in the form of diagnostic kits

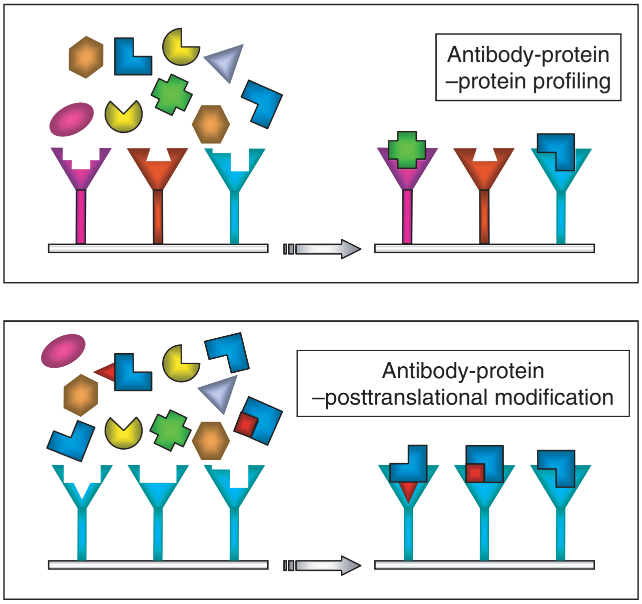

Figure 2 Schematic of antibody arrays and their potential applications. Immobilized antibodies may be used to screen samples such as body fluids or cell lysates in order to assess quantitative changes in protein expression during, for example, disease progression or drug treatment. Through exploitation of the exquisite specificity of antibodies, the posttranslational modifications of proteins may also be determined, shedding light on their activity and the signaling pathways that may be involved in their regulation

cancer (Miller *et al*., 2003), and leukemia (Belov *et al*., 2001) have indicated that the diagnosis and treatment of cancer may be revolutionized as a result of the discoveries made with this technology. However, as the following sections will reveal, there remain many technical difficulties to overcome before protein and antibody arrays become routine tools in the clinical and research environment.

3. Requirements of an array

The basic requirements of an array or chip are apparently simple: a source of specific recognition molecules that can be immobilized in a spatially defined manner, and a method to detect the interaction of the individual molecules in the test mixture with their corresponding recognition molecules on the array. The properties of DNA make it an ideal tool for the specific and quantitative recognition of target nucleic acid sequences. The oligonucleotide or cDNA components of a DNA chip can be readily synthesized in the laboratory, either through plasmid amplification in host cells, PCR, or by direct synthesis onto a solid support (Gao *et al*., 2004; *see also* Article 90, **Microarrays: an overview**, Volume 4). The intermolecular recognition between target and probe is based, in effect, on "linear epitopes" and, thus, retaining a three-dimensional conformation is unnecessary and indeed undesirable. This means that nucleic acid sequences may be immobilized on a solid support

without loss of functionality, and array hybridization may be performed under stringent conditions. Critically, the probes and the targets share their physicochemical properties, which means that every probe will hybridize to their specific target under similar experimental conditions during the screening process. Detection of nucleic acids within the sample is simple because the DNA may be tagged with radioisotopic or fluorescent labels without influencing subsequent interaction with the arrayed DNA. Finally, DNA is relatively resistant to degradation, and the chips, if stored correctly, should have a reasonable shelf life. As will become evident, many of the characteristics of nucleic acids that make them so suitable for analysis by microarray technology do not apply when it comes to the development of protein and antibody arrays.

4. Proteins as elements on an array

Protein and antibody arrays are required to perform rather different analyses, but many of the same principles apply when utilizing protein moieties as the immobilized recognition molecules. The proteins must be generated in reasonable quantities and they must be purified to homogeneity prior to their application to the chip surface. While this can be achieved for a small number of proteins, performing multiple steps on hundreds of proteins in parallel is a major undertaking, especially as each protein may require its own optimized procedures for expression and isolation. Similarly, conventional methods for generating high-quality monoclonal antibodies would be prohibitively time consuming and expensive if they were to be applied to hundreds of protein targets. The proteins that comprise the array must be highly specific, that is, they must be capable of recognizing individual proteins when presented in a complex mixture. Unlike DNA, proteins adopt complex three-dimensional conformations in vivo, and their intermolecular interaction may be perturbed by any of a number of factors that affect the spatial orientation of the molecules. In addition, they are subject to nonspecific interactions when similar epitopes are presented by many different proteins. Finally, the binding of the individual proteins within the sample mixture to the immobilized proteins on the array must occur under similar blocking and washing conditions, not easy to achieve because they are expressing a multitude of physicochemical properties. These are difficult issues to address, but some of the approaches being explored will be described briefly here (Jenkins and Pennington, 2001; Phelan and Nock, 2003; Seong and Choi, 2003).

One approach is to generate libraries of bacteria expressing the proteins of interest via inducible plasmids. The bacteria are cultured in 96-well plate format and many of the steps, from expression and harvesting of the recombinant proteins to spotting on acrylamide-coated slides, are automated. Such an approach has yielded a protein array with over 2400 different human proteins that may be used for screening antibodies for specificity and affinity, and for investigating serum from patients with conditions such as arthritis (Lueking *et al*., 2003). One critical issue with this type of expression platform is that bacteria are unable to perform the full range of posttranslational modifications that are associated with mammalian cells, and thus not all of the bacterially expressed proteins will display the required

intermolecular interactions. Another approach is phage display technology, in which a virus that infects bacteria is genetically manipulated to express a protein of interest on its surface coat (Barbas *et al*., 1991; Clackson *et al*., 1991; Griffiths *et al*., 1994; Huse *et al*., 1989), allowing rapid and potentially parallel manufacture of many proteins. This technology can be used to express proteins or antibody fragments, and the phage can be manipulated to express the proteins fused to tags useful for purification or immobilization. However, the phage must undergo multiple rounds of selection before a protein highly specific for its target is isolated.

One means to avoid the pitfalls associated with proteins as elements on an array is to avoid them altogether. Oligonucleotide aptamers, sequences of nucleic acids that can be engineered to adopt specific three-dimensional conformations, have been used with some success (Cox and Ellington, 2001). All the benefits of working with nucleic acids rather than proteins apply, but the screening process is again laborious, and the proteins most successfully targeted are those that are small and hydrophilic. The approach has been improved recently by the incorporation of a light-reactive nucleotide into the arrayed aptamers, allowing cross-linking to the target protein by UV irradiation and more stringent washing prior to fluorescence detection of bound proteins (Bock *et al*., 2004). Some researchers have begun to exploit the mimetic abilities of inorganic polymers that, once imprinted with the three-dimensional shape of the target protein, can then be used to form the basis of an assay for that protein (Takeuchi *et al*., 1999; Owens *et al*., 1999; Ye and Haupt, 2004). The so-called molecularly imprinted polymers exhibit many useful characteristics, such as stability, resistance to chemical insult, and ability to adopt any conformation required of them. However, because they are not specific for a single protein epitope but recognize the whole protein, they are, in effect, polyclonal and suffer from all the associated problems of cross-reactivity and limited ability to distinguish between alternatively spliced and posttranslationally modified proteins. Nevertheless, it is likely that this technology will continue to be developed and will result in a range of valuable affinity reagents.

5. Immobilization strategies

There are many methods available for the deposition of DNA molecules onto a variety of surfaces without alteration of the molecular properties of the molecules. While some of these may be adapted for the arraying of proteins or antibodies, maintaining the specificity of the capture reagent is much more difficult because the molecular interaction is usually critically dependent on the three-dimensional structure of the protein (*see* Article 32, **Arraying proteins and antibodies**, Volume 5). Irreversible electrostatic binding of proteins to a nitrocellulose-based polymer coated onto glass slides (FAST) allows high density, high-capacity arraying of proteins, but denaturation of the proteins may occur (Stillman and Tonkinson, 2000; Seong and Choi, 2003; Espina *et al*., 2003). Covalent binding directly to substrates such as photolithographically etched nylon or silica surfaces (Blawas and Reichert, 1998; Mooney *et al*., 1996) would probably result in a more stable array, but may also alter the binding properties of the capture reagent. The binding capacity may be increased by modification of the surface of the substrate with

functional groups such as aminosilane (Jenkins and Pennington, 2001; Seong and Choi, 2003). Alternatively, substances such as glutaraldehyde and *N*-succinimidyl-4-maleimidobutyrate may be used as cross-linkers in order to increase accessibility to ligand binding sites by introducing a gap between the substrate surface and the immobilized protein (ShriverLake *et al*., 1997; Seong and Choi, 2003; Blawas and Reichert, 1998; Jenkins and Pennington, 2001; Espina *et al*., 2003).

Immobilization to the solid support may be by passive adsorption, in which the protein to be immobilized is randomly orientated on the array surface: a percentage of the proteins to be immobilized may fortuitously align themselves correctly, but in order to achieve maximum sensitivity of the assay, orientated immobilization is likely to be required (Hodneland *et al*., 2002; Blawas and Reichert, 1998; Peluso *et al*., 2003). Orientation of immunoglobulins is often achieved through the use of bacterial Protein A, G, or L, which display specificity for several regions of mammalian immunoglobulin molecules. These may be engineered to increase their utility in protein arrays: for instance, Protein A has been engineered to express five copies of the immunoglobulin G–binding domain plus a cysteine residue at the C-terminus, the latter to allow strong binding to gold immobilization surfaces (Kanno *et al*., 2000). Orientation of intact antibodies, Fab fragments, or other capture proteins can also be achieved if they are biotinylated and the surface of the array is coated with streptavidin (Peluso *et al*., 2003), but there is a risk that tagging of the proteins may alter their interaction with the protein of interest. Clearly, optimization of the immobilization process is an ongoing task.

6. Detection of interacting proteins

Detection of bound molecules on a DNA microarray is readily achieved, but detection of bound proteins in a rapid and sensitive manner is more problematic (see Haab, 2003 for review and *see* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5). Direct labeling of the sample proteins with fluorescent dyes is already well established for other proteomics approaches such as difference gel electrophoresis (DIGE) (Unlü *et al*., 1997). This technique has been extended to antibody arrays (Haab *et al*., 2001) but may not be entirely appropriate as labeling with fluorescent tags involves chemical modification of the proteins and may adversely influence the interaction of the proteins with their respective recognition molecule on the array. It is also important that the stoichiometry of labeling is consistent, that is, the ratio of protein molecules to fluorescent tag molecules is reasonably consistent for any individual protein in any complex mixture. To this end, the reaction conditions must be optimized to ensure that as close to complete labeling as possible of amino groups is achieved so that any differences in signal intensity observed between control and test arrays are due to differences in protein level rather than labeling efficiency. However, the greater the degree of protein modification, the higher is the likelihood that the protein–protein interaction will be disrupted. As methods to manufacture targeted antibodies develop, it may be possible to generate a panel of affinity reagents that recognize their cognate protein in its labeled rather than native state, sidestepping problems associated with

protein modification. However, the sensitivity of direct labeling and detection with a fluorophore is such that a large array with low-density features may be required at a time when miniaturized and high-density arrays are the preferred option.

Small tags such as biotin may be used to label the protein mixture to be probed, and those proteins captured on an array may then be detected using a molecule that displays high affinity for biotin, such as streptavidin. Modification with biotin tends to have less of an impact on protein conformation than labeling with large fluorophores and is therefore less likely to disrupt protein–protein interaction. The streptavidin is labeled either with a fluorophore or with an enzyme such as peroxidase, the latter allowing amplification of the signal on incubation with a color-producing substrate. Thus, indirect detection of captured proteins can have the advantage of increased sensitivity compared to direct detection. No modification of the sample proteins would be required if a labeled antibody specific for the proteins of interest was available, but in the case of antibody arrays, this would mean that two highly specific antibodies raised in different hosts would be required. As has already been discussed, generating a single antibody with the required characteristics can be a problem.

While the above methods for detection of the captured moiety are routine and thus have been optimized for similar assays such as Western blotting or enzyme-linked immunosorbant assay (ELISA), a method to detect captured proteins directly and with high sensitivity without the need to modify the sample would be ideal. Biosensors have been designed that measure the amount of protein captured on a sensing layer by detecting changes in the emission of light, heat, electrons, or ions (Nice and Catimel, 1999; Ziegler and Göpel, 1998; Jenkins and Pennington, 2001). For example, in a surface plasmon resonance (SPR) detector, a glass slide is coated with metal and protein immobilized to it via an ester linkage. When the protein of interest is captured, the mass at the glass surface is increased, and this causes a change in the refractive index of the glass that can be related to the amount of protein bound. This technology forms the basis of the BIAcore system (**www.biacore.com**) (Nelson *et al*., 2000; Nice and Catimel, 1999; Karlsson, 2004). The current applications of this system to proteomics include the screening of aptamers and antibodies to be used as capture reagents, confirmation of interactions between proteins and other moieties and, by coupling directly to a mass spectrometer, identification of unknown interaction partners (Karlsson, 2004). However, if a suitable degree of miniaturization could be achieved, detection methods such as this could be applicable to protein and antibody arrays.

7. Conclusion

Despite the many technical difficulties with the production of protein and antibody arrays that have been summarized in this article, the first commercially available tools for protein and antibody arrays are beginning to appear on the market. Thus, slides may be purchased that are suitable for the immobilization of proteins, and a range of strategies may be used to deposit the proteins of interest in a spatially defined manner, allowing researchers to produce their own arrays. Alternatively, some companies offer a service whereby customized antibodies or peptides are

generated for subsequent incorporation into a chip, and others offer premade arrays of about 2000 "functional" proteins. While significant progress has been made, further developments in all aspects of array production will be required before protein and antibody arrays are sufficiently reliable, cheap, and data-rich to elicit a revolution in our understanding of biological systems comparable to that brought about by DNA chip technology.

Specialist Review

Two-dimensional gel electrophoresis

Angelika Görg and Walter Weiss
Technische Universität München, Freising-Weihenstephan, Germany

Michael J. Dunn
Proteome Research Centre, University College Dublin, Conway Institute for Biomolecular and Biomedical Research, Dublin, Ireland

1. Introduction

Two-dimensional gel electrophoresis (2DE) with immobilized pH gradients (IPGs) combined with protein identification by mass spectrometry (MS) is currently the workhorse for proteomics. In spite of new promising technologies that have emerged (MudPIT, stable isotope labeling, arrays) (*see* Article 13, **Multi-dimensional liquid chromatography tandem mass spectrometry for biological discovery**, Volume 5, Article 23, **ICAT and other labeling strategies for semi-quantitative LC-based expression profiling**, Volume 5, and Article 24, **Protein arrays**, Volume 5), 2DE is currently the only technique that can be routinely applied for parallel quantitative expression profiling of large sets of complex protein mixtures such as whole-cell lysates.

Whatever technology is used, proteome analysis is technically challenging, because the number of different proteins expressed at a given time under defined biological conditions is likely to be in the range of several thousand for simple prokaryotic organisms up to at least 10 000 in eukaryotic cell extracts. Moreover, current proteomic studies have revealed that the majority of identified proteins are abundant "housekeeping" proteins that are present in numbers of 10^5 to 10^6 copies per cell, whereas proteins such as receptor molecules that are present in much lower concentrations (typically <100 molecules per cell) are usually not detected. Consequently, improved methods for enrichment of low-abundance proteins are required, such as prefractionation procedures, as well as more sensitive detection and quantitation methods.

2DE couples isoelectric focusing (IEF) and sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) to resolve proteins according to two independent parameters, that is, isoelectric point (pI) in the first dimension and molecular mass (M_r) in the second. Depending on the gel size and pH gradient used, 2DE can resolve more than 5000 proteins simultaneously ($\sim$2000 proteins

routinely), and can detect <1 ng of protein per spot. Furthermore, it delivers a map of intact proteins, which reflects changes in protein expression level, isoforms or posttranslational modifications. This is in contrast to LC-MS/MS-based methods, which perform analysis on peptides, where M_r and pI information is lost, and where stable isotope labeling is required for quantitative analysis.

The former limitations of carrier ampholyte-based 2DE (O'Farrell, 1975) with respect to reproducibility, resolution, separation of very acidic and/or very basic proteins, and sample loading capacity have been solved by the introduction of IPGs for the first dimension of 2DE (Görg *et al*., 1988). Narrow-overlapping pH gradients provide increased resolution ($\Delta pI = 0.001$) and detection of low-abundance proteins, whereas alkaline proteins up to pH 12 have been separated under steady state conditions (Görg *et al*., 2000; Wildgruber *et al*., 2002; Drews *et al*., 2004).

The analysis of very hydrophobic proteins such as integral membrane proteins remains a challenge for both 2DE and LC-based proteomic approaches. Currently, the best strategy is the combination of SDS-PAGE analysis of membrane fractions in combination with LC-MS/MS. This method has been termed *geLC-MS/MS* (Li *et al*., 2003).

2. 2DE-MS proteomic workflow

The major steps of the 2DE-MS workflow are

- sample preparation/solubilization
- protein separation by 2DE
- protein detection and quantitation
- computer-assisted analysis of 2DE patterns
- protein identification and characterization
- 2D protein database construction.

and will be discussed in the following sections.

Sample preparation should be as simple as possible to increase reproducibility. Although many "standard" protocols for sample preparation have been published, these protocols must be optimized for the type of sample to be analyzed. Some general recommendations, however, can be made: protein modifications during sample preparation must be minimized, because they might result in artifactual spots on 2D gels. In particular, proteolytic enzymes in the sample must be inactivated. Samples containing urea must not be heated to avoid charge heterogeneities caused by carbamylation of the proteins by isocyanate formed in the decomposition of urea (Dunn, 1993). The three fundamental steps in sample preparation are cell disruption, inactivation and or removal of interfering substances, and solubilization of the proteins (*see* Article 2, **Sample preparation for proteomics**, Volume 5).

Cell disruption can be achieved by osmotic lysis, freeze-thaw cycling, detergent lysis, enzymatic lysis of the cell wall, sonication, grinding with (or without) liquid nitrogen, high pressure (e.g., French press), homogenization with glass beads and a bead beater, nitrogen cavitation, or a rotating blade homogenizer. These methods can be used individually or in combination.

During or after cell lysis, *interfering compounds* such as proteolytic enzymes, salts, lipids, nucleic acids, polysaccharides, and plant phenols have to be inactivated or removed. The two most important parameters are *salt* and *proteolysis*. *Proteases* must be inactivated to prevent protein degradation that otherwise may result in artifactual spots and loss of high M_r proteins. Protease inhibitors are usually added, but they may modify proteins and cause charge artifacts. Other remedies are boiling the sample in SDS-buffer (without urea!), or inactivating proteases by low pH (e.g., precipitating with ice-cold trichloroacetic acid (TCA)). It should be kept in mind that it may be rather difficult to completely inactivate all proteases. TCA/acetone precipitation is very useful for minimizing protein degradation and removing interfering compounds, such as salt. Attention has to be paid, however, to protein losses due to incomplete precipitation and/or resolubilization of proteins. Moreover, a completely different set of proteins may be obtained by extraction with lysis buffer, depending on whether there was a preceding TCA precipitation step. On the other hand, this effect can be used for the enrichment of very alkaline proteins (such as ribosomal or nuclear proteins) from total cell lysates (Görg *et al*., 2000).

Salt ions may interfere with electrophoretic separation and should be removed if their concentration is too high (>100 mM). Removal can be achieved by precipitation of proteins with TCA or organic solvents (e.g., cold acetone). One alternative is the use of 2D cleanup kits (e.g., Amersham Biosciences). Another is dilution of the sample below a critical salt concentration followed by application of a larger sample volume onto the IPG gel. The sample is "desalted" in the gel by using low voltage at the beginning of the run.

After cell disruption and/or removal of interfering compounds, the individual polypeptides must be *denatured, solublized, and reduced* to disrupt intra- and intermolecular interactions while maintaining the inherent charge properties. The most popular sample solubilization buffer is based on O'Farrell's lysis buffer and modifications thereof (O'Farrell, 1975) (9 M urea, 2–4% CHAPS, 1% dithiothreitol (DTT), 2% (v/v) carrier ampholytes). Unfortunately, urea lysis buffer is not ideal for the solubilization of all protein classes, particularly for membrane or other highly hydrophobic proteins. Improvement in the solubilization of hydrophobic proteins has come with the use of thiourea and new zwitterionic detergents such as sulfobetaines (Luche *et al*., 2003).

3. Prefractionation procedures

Prefractionation can be used to reduce the complexity of the sample, enrich for certain proteins such as low-copy number proteins or alkaline proteins, and to get some information on the topology of the proteins. This can be accomplished by:

- isolation of specific cell types from a tissue, for example, fluorescence activated cell sorting (FACS), or laser capture micro dissection (*see* Article 6, **Laser-based microdissection approaches and applications**, Volume 5);
- isolation of cell compartments and/or organelles, for example, by sucrose gradient centrifugation, or free flow electrophoresis;

- selective precipitation of certain protein classes (e.g., TCA/acetone precipitation for ribosomal proteins);
- sequential extraction procedures with increasingly powerful solubilizing buffers, for example, aqueous buffers, organic solvents (e.g., ethanol or chloroform/methanol), and detergent-based extraction solutions;
- chromatographic or electrokinetic separation methods, such as column chromatography, affinity purification, electrophoresis in the liquid phase and/or IEF in granulated gels.

4. 2DE with IPGs (IPG-Dalt)

IPGs are based on the use of the bifunctional Immobiline reagents, a series of 10 chemically well-defined acrylamide derivatives with the general structure CH_2=CH–CO–NH–R, where R is either a carboxyl or an amino group. These reagents form a series of buffers with different pK values between pK 1 and >12. Because the reactive end of the molecule is copolymerized with the acrylamide matrix, extremely stable pH gradients are generated, allowing true steady state IEF with increased reproducibility, as has been demonstrated in several inter-laboratory comparisons (Corbett *et al*., 1994; Blomberg *et al*., 1995).

The original protocol of 2DE with immobilized pH gradients (IPG-Dalt) was described by Görg *et al*. (1988, updated in 2000 and 2004), summarizing the critical parameters inherent to isoelectric focusing with IPGs and a number of experimental conditions (Figure 1). The first dimension of IPG-Dalt, IEF, is performed in individual, 3-mm wide and up to 24-cm-long IPG gel strips cast on GelBond PAGfilm (laboratory-made or commercial Immobiline Dry-Strips). Samples can be applied either by cup-loading or by in-gel rehydration. For analytical purposes, typically 100 µg of protein can be loaded on an 18-cm-long, wide pH range gradient, and 500 µg on narrow range IPGs. For micropreparative purposes, five to ten times more protein can be applied. After IEF, the IPG strips are equilibrated with SDS-buffer in the presence of urea, glycerol, DTT, and iodoacetamide, and applied onto horizontal or vertical SDS gels in the second dimension (*see* Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5).

The *choice of pH gradient* primarily depends on the sample's protein complexity. *Wide* IPGs, such as IPG 4–7, 4–9, or 3–11, are used to analyze simple proteomes (small genome, organelle, or other subfraction), or to get an overview of a more complex proteome, respectively (Figure 2).

With samples such as total lysates of eukaryotic cells, 2D electrophoresis on a single wide-range pH gradient reveals only a small percentage of the whole proteome. The best remedy, preferably in combination with prefractionation procedures, is to use multiple *narrow overlapping* IPGs ("zoom-in" gels, e.g., IPG 4–5, IPG 4.5–5.5, or 5.0–6.0) and/or extended separation distances to achieve an optimal resolution to avoid multiple proteins in a single spot for unambiguous protein identification and to facilitate the application of higher protein amounts for the detection of minor components (Wildgruber *et al*., 2000; Westbrook *et al*., 2001).

Strongly alkaline proteins such as ribosomal and nuclear proteins with closely related pIs between 10.5 and 11.8 are focused to the steady state by using IPGs

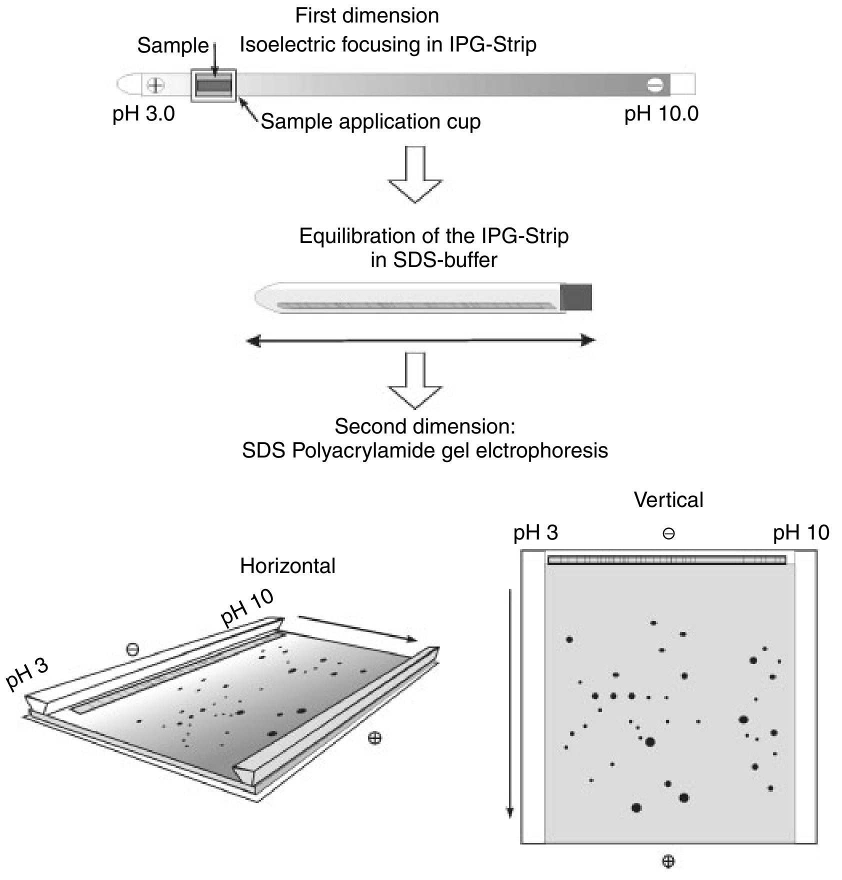

Figure 1 The principle of 2DE with IPGs according to Görg *et al*. 1988, 2000, 2004 (Reproduced by permission of Wiley from Westermeier R and Görg A (2004) Two-dimensional electrophoresis in proteomics. In *Protein Purification, Third Edition*, Janson JC (Ed.), John Wiley & Sons Inc., New York (in press).)

3–12, 6–12, or 9–12 (Wildgruber *et al*., 2002; Drews *et al*., 2004) (Figure 3). For optimized separation, cup-loading at the anode is mandatory, and the use of high voltages (final settings up to 8000 V) is recommended. With narrow gradients between pH 7 and 10, horizontal streaking due to DTT depletion can occur at the basic end. To avoid streaking, the cysteines should be stabilized as mixed disulfides by using hydroxyethyldisulfide reagent (DeStreak^{TM} Amersham Biosciences) in the IPG strip rehydration solution instead of a reductant (Olsson *et al*., 2002).

4.1. *IEF temperature*

Spot positions vary along the pH axis with different applied temperatures (Görg *et al*., 1991). It is thus very important to run the separations at an actively controlled temperature, where 20°C proved to provide the optimal conditions.

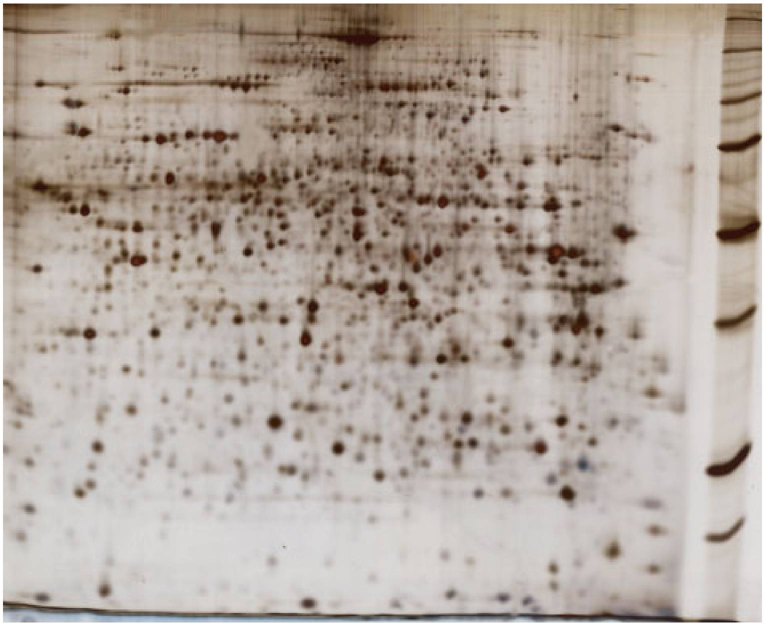

Figure 2 2DE of a TCA-acetone extract of mouse liver proteins, separated by IEF in a 24-cm-long IPG strip containing a nonlinear pH gradient 3–11, followed by SDS-PAGE in a vertical 12.5% gel. Protein detection by silver staining (Reproduced by permission of Wiley from Westermeier R and Görg A (2004) Two-dimensional electrophoresis in proteomics. In *Protein Purification, Third Edition*, Janson JC (Ed.), John Wiley & Sons Inc., New York (in press).)

4.2. *Optimization of focusing conditions*

Settings are usually limited to 50 µA per strip and 150 V to avoid Joule heating, because the conductivity is initially high due to salts. As the run proceeds, the salt ions migrate to the electrodes, resulting in decreased conductivity and allowing high voltages to be applied. Final settings up to 8000 V are particularly used for zoom-in gels and alkaline pH gradients. The longer the IPG strip and the narrower the pH gradient, the more volt-hours are required to achieve steady state separation for high reproducibility (Görg *et al*., 2000; Görg *et al*., 2004).

4.3. *Storage of IPG strips after IEF*

If the second dimension cannot be performed directly after IEF, the IPG strips should be immediately frozen and stored at −70°C between two plastic sheets.

5. Equilibration of IPG gel strips

Before the second-dimension separation, it is essential that the IPG strips are equilibrated to allow the separated proteins to fully interact with SDS. Relatively

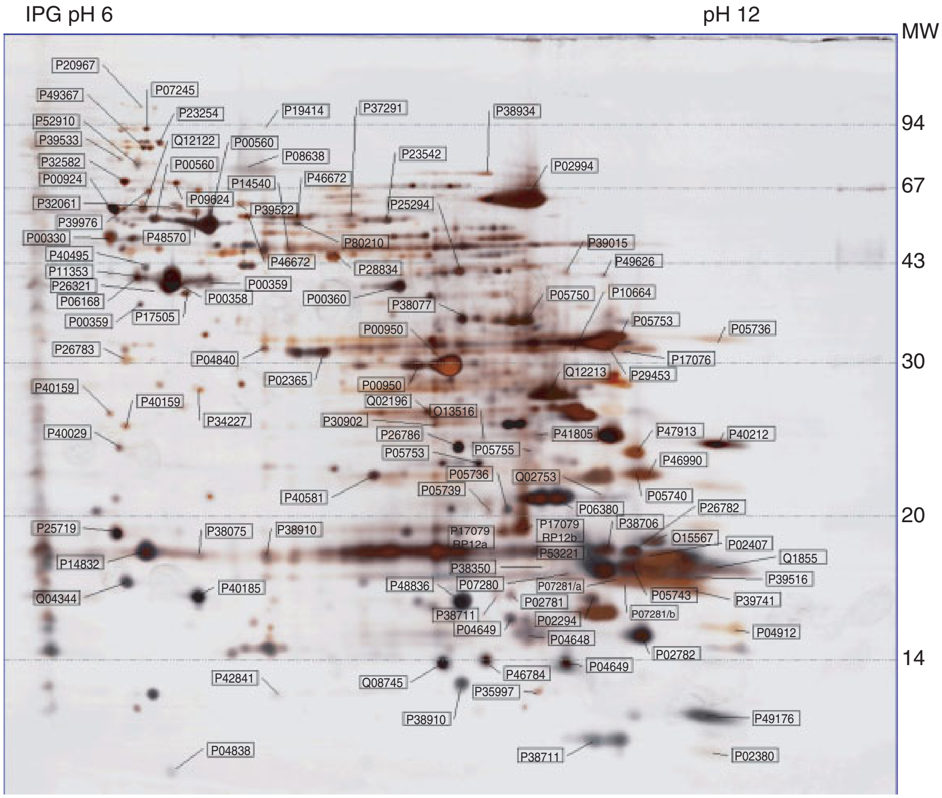

Figure 3 2DE of a TCA-acetone extract of *Saccharomyces cerevisiae* proteins, separated by IEF in an 18-cm-long IPG strip containing a linear pH gradient 6–12, followed by SDS-PAGE in a vertical 15% gel. Protein detection by silver staining showing the 106 mapped and identified spots annotated by Swiss-Prot accession numbers (Reproduced by permission of Wiley-VCH from Wildgruber R, Reil G, Drews O, Parlar H and Görg A (2002) Web-based two-dimensional database of *Saccharomyces cerevisiae* proteins using immobilized pH gradients from pH 6 to pH 12 and matrix-assisted laser desorption/ionization-time of flight mass spectrometry. *Proteomics,* **2**, 727–732.)

long equilibration times (10–15 min), as well as urea and glycerol (to reduce electroendosmotic effects) are required to improve protein transfer from the first to the second dimension. The best protocol by far is to incubate the IPG strips for 10–15 min in the Tris-HCl buffer originally described by Görg *et al*. (1988) (50 mM Tris-HCl (pH 8.8), containing 2% (w/v) SDS, 1% (w/v) dithiothreitol (DTT), 6 M urea and 30% (w/v) glycerol). This is followed by a further 10–15 min equilibration in the same solution containing 4% (w/v) iodoacetamide instead of DTT. The latter step is used to alkylate any free DTT, as otherwise it migrates through the second-dimension SDS-PAGE gel, resulting in an artifact known as *point streaking* that can be observed after silver staining. More importantly, the iodoacetamide alkylates sulfhydryl groups and prevents their reoxidation; this step is highly recommended for subsequent spot identification by mass spectrometry. After equilibration, the IPG strips are applied onto the surface of the second-dimension horizontal or vertical SDS-PAGE gels.

6. Second dimension: SDS-PAGE

SDS-PAGE can be performed on horizontal or vertical systems. Horizontal setups are ideally suited for ready-made gels (e.g., ExcelGel SDS; Amersham Biosciences), whereas vertical systems are preferred for multiple runs in parallel, in particular for large-scale proteome analysis which usually requires simultaneous electrophoresis of batches of second-dimension SDS-PAGE gels for higher throughput and maximal reproducibility. The most commonly used buffers for the second dimension of 2DE are the discontinuous buffer system of Laemmli (1970) and modifications thereof, although for special purposes other buffer systems are employed, such as borate buffers for the separation of highly glycosylated proteins (Patton *et al*., 1991), or Tris-Tricine buffer systems for the separation of low molecular mass (3–30 kDa) polypeptides (Schägger and von Jagow, 1987). Typically, gel sizes of $20 \times 25\,\text{cm}^2$ and a gel thickness of 1.0 mm are recommended. In contrast to horizontal SDS-PAGE systems, it is not necessary to use stacking gels with vertical setups, as the protein zones within the IPG strips are already concentrated and the nonrestrictive, low polyacrylamide concentration IEF gel acts as a stacking gel (Dunn and Görg, 2001).

7. Difference gel electrophoresis (DIGE)

A bottleneck for high-throughput proteomic studies is image analysis. In conventional 2D methodology, protein samples are separated on individual gels, stained, and quantified, followed by image comparison with computer-aided image analysis programs. Because multistep 2DE technology often prohibits different images from being perfectly superimposable, image analysis is frequently very time consuming. To shorten this laborious procedure, Ünlü *et al*. (1997) have developed a method called *fluorescent difference gel electrophoresis* (DIGE), in which two samples are labeled in vitro using two different fluorescent cyanine dyes (CyDyes, Amersham Biosciences) differing in their excitation and emission wavelengths, then mixed before IEF and separated on a single 2D gel. After consecutive excitation with both wavelengths, the images are overlaid and subtracted, whereby only differences (e.g., up- or downregulated, and/or posttranslationally modified proteins) between the two samples are visualized (Figure 4). Owing to the comigration of both samples, methodological variations in spot positions and protein abundance are excluded, and, consequently, image analysis is facilitated considerably (*see* Article 25, **2D DIGE**, Volume 5 and Article 30, **2-D Difference Gel Electrophoresis – an accurate quantitative method for protein analysis**, Volume 5).

A third cyanine dye is now available, which makes it possible to include an internal standard, which is run on all gels within a series of experiments. This internal standard, typically a pooled mixture of all the samples in the experiment labeled with this dye, is used for normalization of data between gels thereby minimizing experimental variation and increasing the confidence in matching and quantitation of different gels in complex experimental designs (Alban *et al*., 2003). Applications that profit from the DIGE system include the investigation of differential protein

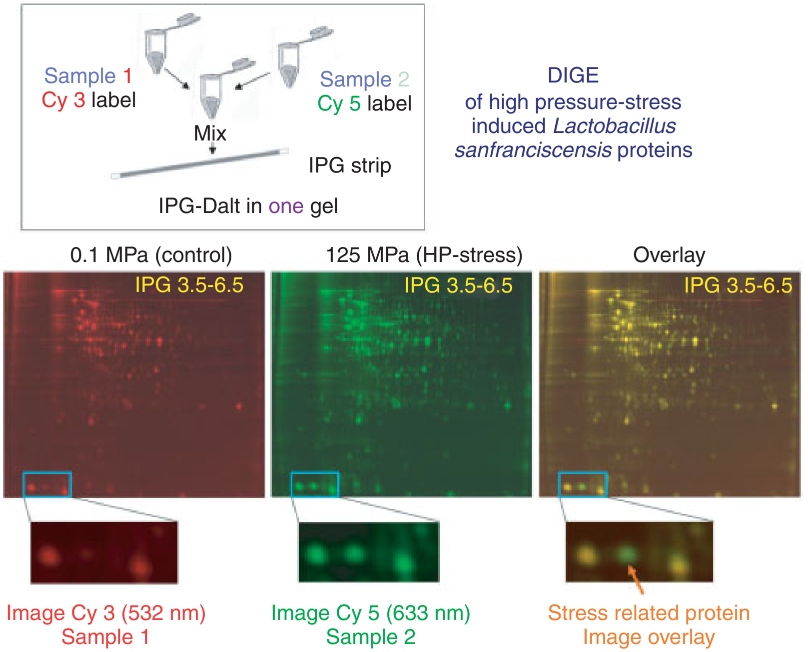

Figure 4 DIGE of high-pressure inducible *Lactobacillus sanfranciscensis* proteins. Samples (Control (at 0.1 Mpa) and high-pressure stressed (at 125 MPa)) were labeled in vitro with two different fluorescent cyanine dyes (Cy3 and Cy5, respectively) differing in their excitation and emission wavelengths. The samples were mixed, and the mixture was separated on a single 2DE gel. After consecutive excitation with both wavelengths, the resultant gel images were overlayed to visualize differences (e.g., up- or downregulated proteins) between the samples (Reproduced by permission of Cold Spring Harbor Laboratory Press from Görg A, Drews O and Weiss W (2004) Separation of proteins using two-dimensional gel electrophoresis. In *Purifying Proteins for Proteomics*, Simpson RJ (Ed.), Cold Spring Harbor Laboratory Press, New York, pp. 391–430.)

expression of samples generated under various prespecified conditions, the comparison of extracts, and the analysis of biological variance. In short, all analyses in which 2D gels need to be compared are simplified and accelerated by this method.

8. Protein visualization

After 2DE, the separated proteins have to be visualized, either by "universal" or by specific staining methods. The most important properties of stains are high sensitivity (low detection limit), high linear dynamic range (for quantitative accuracy), reproducibility, and compatibility with postelectrophoretic protein identification procedures, such as mass spectrometry (Dunn, 1993; *see also* Article 27, **Detecting protein posttranslational modifications using small molecule probes and multiwavelength imaging devices**, Volume 5). Unfortunately, currently no staining method meets all requirements for proteome analysis.

Universal detection methods of proteins on 2D gels include staining with anionic dyes (e.g., Coomassie Blue), negative staining with metal cations (e.g., zinc imidazole), silver staining, fluorescence staining or labeling, and radioactive isotopes, using autoradiography, fluorography, or PhosphorImaging (Patton, 2002). For most of these staining procedures, the resolved polypeptides have to be fixed in solutions such as in ethanol/acetic acid/ H_2O for at least several hours (but usually overnight) before staining to remove any compounds (e.g., carrier ampholytes, detergents) that might interfere with detection.

Specific staining methods for detection of posttranslational modifications (e.g., glycosylation, phosphorylation) are employed either directly in the 2DE gel, or after transfer (blotting) onto an immobilizing membrane. The blotted proteins can be probed with specific antibodies (e.g., against phosphotyrosine residues) or with lectins (against carbohydrate moieties).

9. Image analysis

The major steps of computer-aided image analysis include (1) data acquisition, (2) spot detection and quantitation, (3) pattern matching, and (4) database construction (Dowsey *et al*., 2003; *see also* Article 26, **Image analysis**, Volume 5).

Currently, several 2D image analysis software packages are commercially available. Programs have been continuously improved and enhanced over the years in terms of faster matching algorithms with lesser manual intervention, and with focus on automation and better integration of data from various sources. New 2D software packages have also emerged which offer completely new approaches to image analysis and novel algorithms for more reliable spot detection, quantitation, and matching. Several programs include options such as control of a spot cutting robot, automated import of protein identification results from mass spectrometry, superior annotation flexibility (e.g., protein identity, mass spectrum, intensity/quantity, links to the Internet), and/or multichannel image merging of up to three different images to independent color channels for fast image comparison.

10. Protein identification from 2D gel spots

Mass spectrometry has become the technique of choice for identification of proteins from excised 2D gel spots as these methods are very sensitive, require small amounts of sample (femtomole to attomole concentrations) and have the capacity for high-sample throughput (Aebersold and Mann, 2003; *see also* Article 31, **MS-based methods for identification of 2-DE-resolved proteins**, Volume 5). Recent advances in mass spectrometry also allow the investigation of posttranslational modifications including phosphorylation and glycosylation (Mann and Jensen, 2003; Kalume *et al*., 2003) (*see* Article 61, **Posttranslational modification of proteins**, Volume 6, Article 62, **Glycosylation**, Volume 6, Article 63, **Protein phosphorylation analysis by mass spectrometry**, Volume 6, and Article 73, **Protein phosphorylation analysis – a primer**, Volume 6). Peptide mass fingerprinting (PMF) is typically the primary tool for protein identification (*see* Article 3, **Tandem**

mass spectrometry database searching, Volume 5, Article 7, **Time-of-flight mass spectrometry**, Volume 5, Article 14, **Sample preparation for MALDI and electrospray**, Volume 5, Article 16, **Improvement of sequence coverage in peptide mass fingerprinting**, Volume 5, and Article 75, **Mass spectrometry**, Volume 6). This technique is based on the finding that a set of peptide masses obtained by MS analysis of a protein digest (usually trypsin) provides a characteristic mass fingerprint of that protein. The protein is then identified by comparison of the experimental mass fingerprint with theoretical peptide masses generated in silico using protein and nucleotide sequence databases. This approach proves very effective when trying to identify proteins from species whose genomes are completely sequenced, but is not so reliable for organisms whose genomes have not been completed.

If it proves impossible to identify a protein based on PMF alone, it is then essential to obtain amino acid sequence information. This is most readily accomplished with MALDI-MS with postsource decay (PSD) or chemical assisted fragmentation (CAF), or by using tandem mass spectrometry. MS/MS takes advantage of two-stage MS instruments, either MALDI-TOF-TOF-MS/MS or ESI-MS/MS triple quadrupole, ion-trap or Q-TOF machines (Article 8, **Quadrupole mass analyzers: theoretical and practical considerations**, Volume 5, Article 9, **Quadrupole ion traps and a new era of evolution**, Volume 5, and Article 10, **Hybrid MS**, Volume 5) to induce fragmentation of peptide bonds. One approach is to generate a short partial sequence or 'tag', which is used in combination with the mass of the intact parent peptide ion to provide significant additional information for the homology search. A second approach uses a database searching algorithm SEQUEST to match uninterpreted experimental MS/MS spectra with predicted fragment patterns generated in silico from sequences in protein and nucleotide databases (*see* Article 4, **Interpreting tandem mass spectra of peptides**, Volume 5).

11. 2D PAGE databases

Currently, enormous efforts are being undertaken to display and analyze with 2D PAGE the proteomes from a large number of organisms, ranging from *organelles* such as mitochondriae, nuclei or ribosomes to simple *prokaroytes* including *Escherichia coli*, *Bacillus subtilis*, *Haemophilus influenzae*, *Mycobacterium tuberculosis,* and *Helicobacter pylori*, to *single-celled eukaryotes* such as the yeast *Saccharomyces cerevisiae* (Figure 3), to *multicellular organisms*, for example, *Caenorhabditis elegans, plants* such as rice (*Oryza sativa*) or *Arabidopsis thaliana*, and *mammalian cells and tissues* including rat and human heart, mouse and human liver, mouse and human brain, different cancer cell lines, HeLa cells, human fibroplasts, human keratinocytes, rat and human serum and so on. Most of these and many other studies in progress are summarized at **www.expasy.org/ch2d/2d-index.html** ("WORLD-2DPAGE Index to 2D PAGE databases"). The Proteomics Standards Initiative (PSI) aims to define community standards for data representation in proteomics to facilitate data comparision, exchange, and verification (**http://psidev.sourceforge.net/**).

12. Concluding remarks

Although we have today a diversity of emerging proteomic platforms, there is still no generally applicable method that can replace 2DE in its ability to simultaneously separate and display several thousand proteins from complex samples such as microorganisms, cells, and tissues. 2DE using IPGs in the first dimension (IPG-Dalt) has proven to be extremely flexible with respect to the requirements of proteome analysis. Although by no means perfect, IPG-Dalt coupled with mass spectrometry remains the core technology for separating and identifying complex protein mixtures in proteomic projects at least for the foreseeable future.

Specialist Review

ICAT and other labeling strategies for semiquantitative LC-based expression profiling

Connie Byrne and Gerard Cagney
University College Dublin, Dublin, Ireland

1. Introduction

Comprehensive proteome analysis requires the identification and quantification of all the proteins in an experimental or clinical sample. This is very much an ideal, because such samples often consist of thousands of proteins spanning a range of biophysical and biochemical properties, and that vary in abundance by many orders of magnitude. Fortunately, developments in protein and peptide ionization linked to mass spectrometry (MS) have made the identification of proteins almost routine (*see* Article 31, **MS-based methods for identification of 2-DE-resolved proteins**, Volume 5). However, only a single peptide or protein (or small number) is usually presented to the MS detector at a time. For over two decades, two-dimensional (2D) gels have been the method of choice for separating proteins (*see* Article 22, **Two-dimensional gel electrophoresis**, Volume 5), but separation strategies based on liquid chromatography (LC) are increasingly common. The LC apparatus may be interfaced directly to the instrument during electrospray experiments (Whitehouse *et al*., 1985). The resolving power of LC is based on factors that include the type of separation media, the solvent flow rate, and the gradient profile. Often, an orthogonal separation step is necessary to separate peptides in complex mixtures. Several configurations have been described (reviewed in Aebersold and Mann, 2003), with two approaches particularly common in recently published large-scale shotgun proteomics experiments. The first involves separating intact proteins using conventional SDS-PAGE gels before digestion and analysis by LC-MS (e.g., Lasonder *et al*., 2002), while another approach involves separation of peptides by ion exchange with LC in a single biphasic capillary column that acts as the electrospray source (Multidimensional Protein Identification Technology, “MUDPIT”; Link *et al*., 1999).

Very large numbers of proteins can be identified in individual samples using these approaches. In fact, experiments identifying thousands of proteins have now been described (e.g., Lasonder *et al*., 2002; Washburn *et al*., 2001; Schirle *et al*., 2003). However, in order to compare the states of the proteome of two or more samples, the quantity as well as the identity of each protein must be determined. Measurement of protein quantity is normally carried out by methods specific for a single protein:

Western blot, ELISA, or other immunological assays. High-throughput methods to estimate the abundance of large numbers of proteins in a single experiment have so far mostly used stable isotope-labeling methods (Hamdan and Righetti, 2002; Regnier *et al*., 2002). Isotopically labeled variants of proteins and peptides are readily detected in mass spectrometers because they vary in mass while having similar chemical properties. Here we describe general experimental strategies for semiquantitative proteomics involving LC-MS, issues to consider when carrying out such experiments, and some examples of the use of these approaches.

Two further comments should be made by way of introduction. First, although matrix-assisted laser desorption ionization (MALDI) MS does not use a direct LC interface to the instrument and as a method is not discussed here, the principles of stable isotope labeling for quantitative proteomics may equally be applied to MALDI-based instruments. Second, differential proteomics experiments attempt to answer the question "What protein levels are different in Sample A compared to Sample B?" However, other factors need to be considered when discussing "expression" proteomics, because this phrase implies some knowledge of the contribution of the synthesis and degradation rates of individual protein to the abundance of those proteins. While we will concern ourselves primarily with technical methods for measuring protein relative abundance, a useful discussion of these concepts can be found in Julka and Regnier (2004).

2. Strategies

There are two ways to experimentally introduce stable isotopes to the proteome (Figure 1). Using the first method, labeled amino acids are incorporated into the media of a cultured experimental system (in vivo). The second type of approach involves incorporating the label at the end of the experiment by chemical or enzymatic means (in vitro). In both cases, two (or more) samples are differentially labeled so that the signal of the corresponding peptides can be compared in the mass spectrometer to estimate their relative abundance. For this reason, an ideal semiquantitative proteomics strategy will have the following features:

- global labeling of all peptides or proteins to completion;
- a mass difference between the sister peptides where the heavier species is beyond the isotope shoulder of the lighter species;
- no detrimental effect of label incorporation on recovery or cleanup steps, mobility in chromatography steps, or ionization during MS;
- simple inexpensive experimental procedure that is easy to carry out on many samples in an identical manner, using any type of experimental model or clinical sample.

2.1. *In vivo methods*

In vivo methods are potentially global in that there is an opportunity for an entire proteome to become labeled with an amino acid containing ^{15}N or ^{13}C (Table 1).

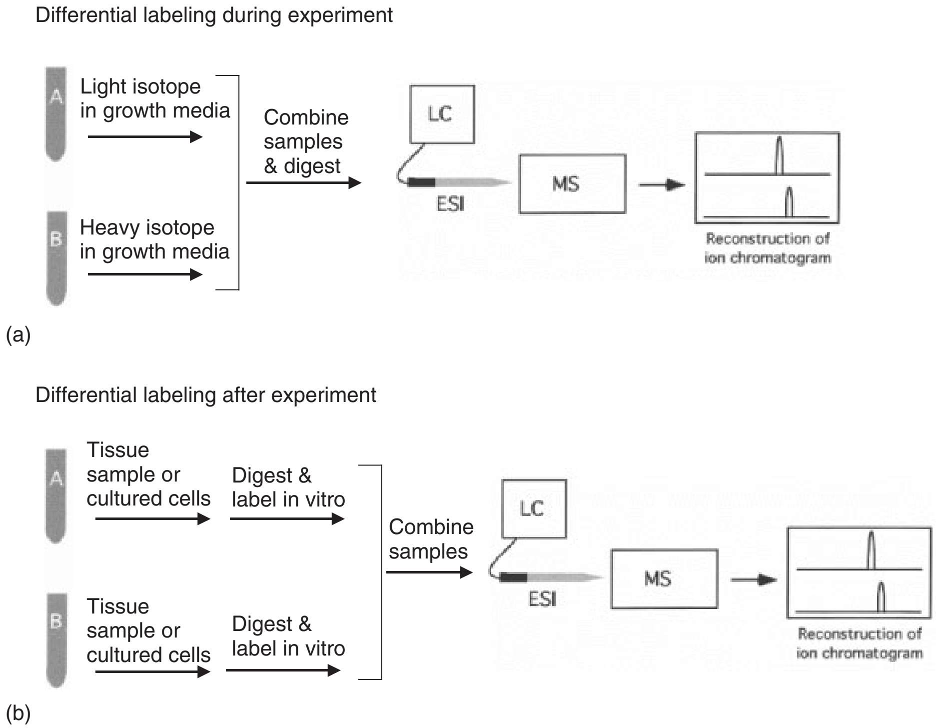

Figure 1 Differential labeling strategies for quantitative proteomics. The label may be incorporated in vivo if the experimental model may be cultured (a). Alternatively, experimental or clinical samples may be labeled in vitro (b)

The organism or cell is grown in culture long enough to allow complete incorporation of the labeled amino acid, and can then be used to compare with a strain grown on normal media. Advantages of this technique are that no chemical labeling or affinity purification steps are required, the method is compatible with virtually all cell culture conditions (including primary cells), and is relatively convenient and inexpensive. The method has been used with microbial organisms (Oda *et al*., 1999; Smith *et al*., 2002; Washburn *et al*., 2002), mammalian cells (Conrads *et al*., 2001), and even small animals fed with labeled yeast or bacteria (Krijgsveld *et al*., 2003).

Initially, ^{15}N media was used to grow microbes (Lahm and Langen, 2000) but a disadvantage of this method is that the exact number of labeled atoms in each peptide can only be inferred once the amino acid sequence is known. Others have used ^{2}H- or ^{13}C-labeled amino acids. The laboratory of Matthias Mann introduced the term SILAC (stable isotope labeling by amino acids in cell culture) in two elegant studies using mammalian cells (Ong *et al*., 2002; Ong *et al*., 2003). ^{13}C-labels were found to be superior to ^{2}H-labeled amino acids because they coelute during reversed-phase chromatography. When "sister" peptides (labeled and unlabeled) do not coelute, it makes relative analysis more complicated (see below). Deuterated amino acids are cheaper than ^{13}C-labeled ones; therefore, work that does not require the high quantitation precision afforded by the ^{13}C6-Arg method can be more economically performed using deuterated amino acids.

Table 1 Labeling technologies for quantitative proteomics

Method	Labeling reagent	Mass difference (Da)	Labeling chemistry	Labeled residue	Labeling step	Comments	References
ICAT	ICAT reagent (8 × ^{2}H)	+8	Thiol	Cysteine	In vitro	Solution phase	Gygi *et al*. (1999)
Cleavable ICAT	Cleavable and solid-phase ICAT reagent (7–9 × ^{13}C)	+7 to +9	Thiol	Cysteine	In vitro	Solid phase	Hansen *et al*. (2003); Zhou *et al*. (2002)
iTRAQ™	iTRAQ™ reagents	+1, +2, +3, +4 for each of the four labels	Amine	Lysine	In vitro	Commercially available (Applied Biosystems)	**www.appliedbiosystems.com**
O18	$H_2{}^{18}O$	+4	Carboxyl	C-terminal carboxylic acid generated by trypsin hydrolysis	In vitro	Drying step required, sometimes reduced efficiency if peptides fail to resuspend	Reynolds *et al*. (2002)
N15	^{15}N	Sequence dependent	In vivo incorporation		In vivo	Restricted to organisms that can be grown in defined media	Lahm and Langen (2000)
SILAC	$^{13}C6$-Arginine	+6	In vivo incorporation	Arginine	In vivo	SILAC	Ong *et al*. (2003)
	D3-Leucine	+3	In vivo incorporation	Leucine	In vivo	SILAC	Ong *et al*. (2002)
MCAT	*o*-methylisourea	+42	Guanidation	C-terminal lysine	In vitro		Krause *et al*. (1999)
Succinimide	($^{2}H_3$)-*N*-acetoxysuccinimide	+42 (arginine labeling) +84 (lysine labeling)	Acylation	Lysine and arginine	In vitro		Ji *et al*. (2000)

2.2. In vitro methods

Labeling using $H_2{}^{18}O$ incorporation is an extremely valuable method for semi-quantitative proteomics. The oxygen atom can be incorporated into peptide C-termini during peptide bond hydrolysis by trypsin, a routine step in proteomics experiments. The enzymology of this reaction has been extensively studied by Catherine Fenselau and others (Yao *et al*., 2001; Reynolds *et al*., 2002; Yao *et al*., 2003) and the incorporation ^{18}O of works for other proteases including chymotrypsin and endoglycosidase Lys C. Two ^{18}O atoms are normally incorporated, generating a 4-Da shift in the mass of the heavier species. This method can also result in improved sequence assignment during peptide sequencing by tandem MS because the ^{18}O atoms label the C terminus of the peptide fragment ions, resulting in specific shifting of the y-series (Schnolzer *et al*., 1996; Shevchenko *et al*., 1997). The method relies on replacement of normal water with ^{18}O-containing water for the labeled sample, in turn requiring a drying step. This can cause problems if the peptides do not resolubilize easily. Other potential problems reported for this method include varying rates of incorporation due to peptide sequence (Schnolzer *et al*., 1996; Stewart *et al*., 2001) and the presence of urea during proteolysis (Regnier *et al*., 2002).

To date, the majority of LC-based expression proteomics studies have used the isotope-coded affinity tag (ICAT) method developed by the Aebersold laboratory (Gygi *et al*., 1999). The ICAT reagent incorporates three moieties: an iodoacteyl group that can react with cysteine side chains under ambient conditions; a linker incorporating eight deuterium atoms; and a biotin group. The biotin allows very efficient recovery of the labeled peptides, while the use of thiol chemistry means that the diversity of the digested proteome is reduced (only peptides containing cysteine are labeled), greatly simplifying analysis by MS and subsequent interpretation. Recently, variant ICAT reagents that incorporate improvements on the original version have been described (Zhou *et al*., 2002; Hansen *et al*., 2003; Li *et al*., 2003; Oda *et al*., 2003). These variants use solid-phase or acid-cleavable reagents to improve peptide recovery and ease of automation, and replace the deuterium label with ^{13}C so that the retention times of heavy/light peptide pairs during reverse-phase chromatography is improved. A side-by-side comparison of the new reagent with the original one showed that it was more efficient and sensitive (Zhou *et al*., 2002). Additional reported advantages of the solid-phase method are that it is faster and simpler, requiring less manual input; it permits more stringent washing conditions to remove noncovalently associated molecules; and owing to the small size and chemical nature of the tag, MS/MS spectra are not complicated by undesirable fragmentation of the label itself.

Several additional stable isotope incorporation strategies have now been described, exploiting different aspects of peptide chemistry. The use of the carboxyl-terminus and cysteine side chains has been described above, but labeling of the amino-terminus, side-chain amino groups, side-chain carboxyl groups, and the side chains of tryptophan has also been used. Excellent review articles have been written describing the merits of these approaches (Julka and Regnier, 2004; Hamdan and Righetti, 2002) and they will only be mentioned briefly here.

Modification of primary amine groups by acylation (sometimes referred to as global internal standard technology, GIST; Chakraborty and Regnier, 2002) is generally easy to carry out. Reaction with ($^2H_3$)-*N*-acetoxysuccinimide generates a +42-Da shift upon binding the N-terminus (Ji *et al*., 2000). The reagent also labels the ε-amino group of lysine, so tryptic peptides ending with lysine will be +84-Da, while those ending in arginine with be +42 Da. In turn, the $^1H_3$- and $^2H_3$-acetate reagents differ by 3 Da. Related methods include modification of terminal amino groups with succinic anhydride (Munchbach *et al*., 2000), 2,4-dinitrofluorobenzene (Chen *et al*., 1999), and phenylisothiocyanate (Mason *et al*., 2003). Methyl esterification of peptide carboxyl groups modifies the side chains of aspartic and glutamic acid residues, as well as the peptide carboxyl terminus, to the corresponding methyl esters. The method was earlier used by mass spectrometrists to facilitate sequencing by tandem MS but reaction with either d0- or d3-methanol can also be used for expression proteomics (Goodlett *et al*., 2001). A strategy to specifically label tryptophan was devised, whereby tryptophan and cysteine residues were reacted with 2,4-dinitrobenzenesulfenyl chloride (containing ^{13}C) followed by reversal of the cysteine labeling by reduction/alkyation (Kuyama *et al*., 2003).

Two other approaches merit mention. The "quaternary amine tag" (QAT) methodology, recently described by Regnier and coworkers (Ren *et al*., 2004), involves reduction of cysteine residues with (3-acrylamidopropyl)trimethylammonium chloride. This procedure has several advantages, including simple chemistry, enhancement of peptide ionization by the tag, and the ability to effectively fractionate complex samples following tagging using cation exchange chromatography. A second approach that has been revisited is guanidination of lysine ε-amino groups. The method was originally used in MALDI MS to enhance signal from lysine-containing peptides, which is normally weaker than peptides containing arginine (Krause *et al*., 1999), but the modification is easy to carry out and adds 42 Da to the modified peptides (Hale *et al*., 2000; Beardsley *et al*., 2000; Brancia *et al*., 2000; Keough *et al*., 2000; Cagney and Emili, 2002).

Recently, a new approach has been described that differs in important respects from the methods described above. Termed tandem mass tagging (TMT), two related reagents are used to label alternative samples (Thompson *et al*., 2003). The TMT reagents have the same overall mass and reactive group (e.g., succinimide ester) so they migrate together during chromatography and have identical peptide reactivities. They have three addition groups: a mass normalization group (e.g., methionine), a cleavage enhancement group (proline), and a sensitization group (e.g., guanidino) which generates the so-called TMT fragment of known mass upon collision-induced dissociation (CID). Relative abundance determination is done by comparing the intensity of the TMT signals – because MS/MS is used for this, signal-to-noise ratio is very high and the sensitivity of this method should be greater than for other methods. Possible shortcomings are the need to carry out MS/MS scans (which limit the number of peptides that may be analyzed per unit time) and the difficulty in making these reagents. A similar set of reagents (iTRAQ) capable of measuring the relative abundance of peptides/proteins from four samples has recently been commercialized by Applied Biosystems.

3. Experimental issues

The power of high-throughput proteomics methods also has limitations. First and importantly, the stable isotope-labeling methods mentioned in this article measure *relative*, not *absolute* abundance. Moreover, they are generally pairwise (i.e., compare two samples with each other in a single experiment). The exceptions include iTRAQ, where up to four differentially labeled reagents have been developed (**www.appliedbiosystems.com**). For pairwise reagents, it is possible to design experiments where, for instance, all samples are compared to a single "reference" sample. Proposals to provide resources for large-scale absolute quantitative proteomics projects have been made recently (Aebersold, 2003).

Second, most of these strategies rely on the experiment and postexperiment handling being exactly equivalent. In cases in which this is in question, it may be desirable to carry out the experiment in both orientations, that is, in duplicate with the heavy/light labels switched in each replicate. The abundance changes can then be averaged. Related to this is the problem of different chromatographic retention times for compounds labeled using deuterium (Zhang *et al*., 2001) or ^{15}N (Conrads *et al*., 2001). This can usually be solved by making an alternative compound using ^{13}C, but sometimes this is not possible, and ^{13}C is much more expensive than deuterium.

Third, the maximum dynamic range that can be measured in a semiquantitative proteomics experiment by MS is inherently limited by the dynamic range of the signal that can be quantified in the mass spectrometer. This relates to another problem: cases where the low-abundance protein is not expressed at all or is expressed at levels that are difficult to distinguish from noise.

Fourth, many artifacts can arise in isotope-labeling experiments. For instance, the proteins or peptides may be incompletely labeled or a subclass of peptide may not be labeled at all. Examples include the ICAT reagent that does not modify cysteine-free peptides (but may be present twice in a peptide containing two cysteines) or ^{18}O-labeling during trypsin hydrolysis, where only a single ^{18}O atom may be incorporated instead of two. Correction for these factors may need to be carried out at the data interpretation stages. In some cases, the labeled peptide may be close in mass to the unlabeled peptide, (e.g., ^{18}O-labeling), resulting in overlap with the isotope shoulder of the light peptide. Again, these factors can be corrected for, but must be considered at the experiment design stage and especially when drawing conclusions at the end of the experiment.

Fifth, on the basis of relative abundance measurements for peptides derived from the same protein (which in general should be present in equimolar amounts), the measurement error for the methods described above are roughly in the range 10–50% (e.g., Shiio *et al*., 2002). This is large, so if the change in expression of an individual protein needs to be known with more precision, additional experiments need to be done. A complicating factor is the potential presence of protein modifications, for instance, cleavage products or phosphorylated peptides. When comparing signal from unmodified peptides derived from two samples, it is normally assumed that this represents all such peptides in the experiment. However, if a fraction of the peptides is actually modified, they may not be considered when determining relative abundance because they appear at a different *m/z* position in the mass spectra, thus overestimating the abundance of the protein in one sample.

However, the data is normally precise enough to establish that a protein is either *up*- or *downregulated*, and when this type of data is available for tens or hundreds of proteins, phenomena at the level of the cell rather than at the merely protein level may become apparent. The study of proteomic effects of Myc oncoprotein induction in rat fibroblasts was an early and impressive illustration of this principle (Shiio *et al*., 2002).

4. Conclusion/Future prospects

By combining stable isotope labeling and peptide reactive chemistries with mass spectrometry, a number of effective strategies of differential proteomics are now available. It is not clear if any of these approaches will become dominant, although the ICAT strategy has been used in a number of important pioneering differential proteomics studies. The choice of strategy will depend on factors such as type of sample (in vitro, clinical), the complexity of the sample, and mass spectrometry facilities. Unlike other differential gene expression studies, where similar reagents have been used for the majority of studies, the diversity of LC-based quantitative proteomics methods may create problems for those attempting to compare results from studies using different methodologies.
